the early 21st century. At the same time, long-term mobile-array observation will become available to allow year-scale collection of natural earthquake records.

1. Introduction

A tsunami is an oceanic gravity wave generated by submarine earthquakes or other geological processes such as volcanic eruptions or landslides. Most tsunamis are caused by shallow large earthquakes and hence are distributed along the subduction zones (Fig. 1). *Tsunami* is a Japanese word meaning harbor wave. Tsunamis are usually small and barely noticed in deep oceans, but they become large and cause damage when they approach coasts or harbors. They are sometimes called seismic sea waves or, erroneously, tidal waves.

Tsunamis have many aspects that are studied by researchers in various fields. Their generation is related to geological processes. Propagation and observation are the domain of

oceanographers, and basic hydrodynamics is needed to understand their characteristics. The coastal behaviors, such as run-up on beaches or resonance in bays, are mostly studied by coastal engineers. City and land-use planners need to consider tsunami risks, and public officials are responsible for tsunami warning and evacuation. In this chapter, the wide range of tsunami phenomena will be reviewed from a seismological viewpoint.

1.1 Examples

1.1.1 The 1993 Okushiri Tsunami

Japan has a long history of tsunami damage. The most recent example is that caused by the Southwest Hokkaido earthquake

FIGURE 1 Distribution of recent Pacific tsunamis. Solid circles indicate the sources of major tsunamis for 1837–1974 (Abe, 1979). Named open circles indicate the tsunamis described in the text.

on 12 July 1993 ($M_W = 7.8$). Okushiri Island, a small island in the Japan Sea, is located within the source area, hence the strong ground shaking was followed, within a few minutes, by tsunami. The island suffered from fire and floods, causing more than 200 casualties. This was probably the best-studied tsunami in terms of field surveys or modeling (Hokkaido Tsunami Survey Group, 1993; Takahashi *et al.*, 1995; Tanioka *et al.*, 1995). The tsunami height was mostly 5–10 m, while the maximum tsunami run-up was measured as more than 30 m.

1.1.2 The 1960 Chilean Tsunami

The largest ($M_W = 9.5$) earthquake in this century occurred off southern Chile on 22 May 1960. The tsunami caused damage on the Chilean coast, including more than 1000 casualties, then propagated across the Pacific Ocean. About 15 h later, the tsunami reached the Hawaiian islands and took about 60 lives. It continued across the Pacific, reaching Japan in about 23 h, and caused more than 100 casualties. The large tsunami in Japan was partly due to a resonance effect: some bays have a shape whose characteristic period coincided with the pre-dominant period (about 1 h) of the trans-Pacific tsunami.

1.1.3 The 1946 Aleutian Tsunami

The Aleutian earthquake of 1 April 1946 was very unusual; it generated huge tsunamis in the Aleutians and Hawaii, even though M_S was only 7.4. This is a typical example of a “tsunami earthquake” that generates much larger tsunamis than expected from seismic waves. The Scotch Cap lighthouse on Unimak Island, about 100 km from the epicenter, apparently had no damage from ground shaking but was totally demolished by the tsunami. The tsunami traveled the Pacific Ocean southward and reached the Hawaiian Islands in the morning of April Fool’s Day. Without any warning, the tsunami took 159 lives in the Hawaiian Islands. A Pacific tsunami warning system was introduced after this tsunami.

1.1.4 The 1958 Lituya Bay Wave

The record of wave height may be the one in Lituya Bay, Alaska. A large strike-slip earthquake ($M_W = 7.9$) occurred on 10 July 1958, and triggered a huge rockslide (total volume of about $3 \times 10^7 \text{ m}^3$) in this 10 km long bay. The rockslide generated water waves that surged up the opposite slope to 520 m altitude, but the large waves were mostly confined in the bay. Hence this example is not considered as a typical tsunami.

1.1.5 The 1998 Papua New Guinea Tsunami

The most recent tsunami hazard was from an earthquake ($M_W = 7.1$) along the northern coast of New Guinea Island on 17 July 1998. The tsunami heights were as large as 15 m around Sissano Lagoon, and the total number of casualties was reported to be more than 2000. The large tsunami ($> 5 \text{ m}$) was limited

to a small region ($\sim 40 \text{ km}$) along the coast, suggesting a local effect of tsunami amplification (Kawata *et al.*, 1999). Post-tsunami marine surveys (Tappin *et al.*, 1999) indicate a focusing of tsunamis due to bathymetry and an involvement of submarine landslides.

2. Size of Tsunamis

2.1 Tsunami Magnitude Scales

2.1.1 Imamura–Iida Scale m

The traditional tsunami magnitude scale is the so-called Imamura–Iida scale, m . Although the original definition was descriptive, the value is approximately equal to

$$m = \log_2 h \quad (1)$$

where h is the maximum run-up height in meters (Iida *et al.*, 1967). This scale is similar to an Earthquake intensity scale, and is especially convenient for old tsunamis from which no instrumental records exist.

Hatori (1979) extended the Imamura–Iida m scale to include far-field tsunami data. He also considered the effect of distance R and constructed an h – $\sqrt{R}$ diagram in log–log scale. The diagram is calibrated in such a way that m becomes 3 when $h = 0.5 \text{ m}$ and $R = 1000 \text{ km}$. The value of m increases one unit when the energy becomes five times (or the amplitude is $\sqrt{5}$ times) larger. This can be expressed as

$$m = 3 + \frac{\log \left[(h/0.5)(R/1000)^{1/2} \right]}{\log \sqrt{5}} \quad (2)$$

where h is in meters and R is in km. This indicates that the decay of tsunami height with distances is $R^{-1/2}$, which is theoretically predicted for nondispersive waves traveling a long distance (Comer, 1980).

2.1.2 Tsunami Intensity

Soloviev (1970) pointed out that the Imamura–Iida m scale is more like an earthquake intensity scale than a magnitude. He also distinguished the maximum tsunami height h and the mean tsunami height $\bar{h}$. He then defined tsunami intensity i as

$$i = \log_2(\sqrt{2} \bar{h}) \quad (3)$$

Comparison of Eqs. (1) and (3) suggests that the mean tsunami height is given as $1/\sqrt{2}$ times the maximum height. The maximum intensity i on the coast nearest to the source is used to quantify the tsunami source.

2.1.3 Tsunami Magnitude M_t

Another magnitude scale M_t , called tsunami magnitude, is defined and assigned for many earthquakes by Abe. The

definition of M_t for a trans-Pacific tsunami is (Abe, 1979)

$$M_t = \log H + C + 9.1 \quad (4)$$

and for a regional ($100 \text{ km} < \Delta < 3500 \text{ km}$) tsunami is (Abe, 1981):

$$M_t = \log H + \log \Delta + 5.8 \quad (5)$$

where H is maximum amplitude on tide gauges in meters, C is a distance factor depending on a combination of the source and the observation points, and Δ is the actual distance in km. The above formulas were calibrated with the moment magnitude scale, M_w of earthquakes. Figure 2 shows comparison of tsunami magnitude M_t and surface wave magnitude M_s for large earthquakes in the last century. Smaller M_s values for events with $M_t > 8$ may be due to the saturation of M_s at around 8.0 (Geller, 1976). Equation (5) indicates that for the same M_t , the tsunami amplitude H decays with $1/\Delta$, which is different from the assumption used for the Imamura–Iida scale m , and may be valid only for regional distances.

2.2 Tsunami Catalogs

The location, size, run-up heights, and damage of past tsunamis have been compiled by several researchers and published as catalogs. For the Pacific tsunamis, Iida *et al.* (1967) contains numerous tsunami height data as far back as AD 173. Russian catalogs (Soloviev and Go, 1974a,b; Soloviev *et al.*, 1992)

FIGURE 2 Relation between M_t (tsunami magnitude) and M_s (surface wave magnitude). A similar plot by Abe (1979) is updated by replacing with more recent estimates of M_s and by adding data for tsunamis since 1979. “Tsunami earthquakes” (above the dashed line) have M_t larger than M_s by more than 0.5 units.

include Pacific tsunami data (excepting for Russia) with some tide gauge records, tabulated tsunami heights, and descriptions for each tsunami. Regional catalogs including tide gauge records were also published for Alaska (Lander, 1996), the west coast of the United States (Lander *et al.*, 1993), and Japan (Watanabe, 1998).

Some of the numerical data can be accessed at the following web sites:

- <http://www.ngdc.noaa.gov/seg/hazard/tsu.shtml>
- <http://tsun.sssc.ru/htdbpac/>

3. Tsunami Observations

3.1 Instrumental Measurements

3.1.1 Tide Gauges in Ports and Harbors

Instrumental measurements of tsunamis have been done in bays or harbors using tide gauges (Fig. 3). In the United States, the National Ocean Service (NOS) has been operating tide gauge stations since the 1850s.

The most traditional and popular tide gauge is a mechanical type with stilling well or tide well. Vertical motion of a float in the well is transmitted by wire to the recorder. For longer-period motions, water level in the well can be assumed to be the same as that of the outer sea. Although the system is robust, the installation (and construction) of tide wells is expensive and periodic maintenance is essential. A cheaper tide gauge is a pneumatic, or gas-purged, pressure gauge, often called a bubbler gauge.

Because the original purpose of tide gauges is to measure ocean tides, whose typical period is 12 h, the sampling interval

FIGURE 3 Schematic illustration of instrumental tsunami observations. Traditional measurements use tide gauges in harbors. Acoustic sensors, either set on the ocean bottom or in the air, are used near shore. In the deep ocean, bottom pressure gauges are used, and the signals are transmitted either via cable or acoustic modem and satellite.

and system response of tide gauges are often inadequate for tsunamis, whose typical period is 5–30 min (Satake *et al.*, 1988).

3.1.2 Acoustic Gauges and Open Coast Measurements

In recent years, tsunami observations on coastal water, outside harbors or bays, have been made to avoid the topographic effects and for the purpose of early detection. Acoustic gauges can be set on the water bottom or above the water surface. The NOS's Next Generation Water Level Measurement System uses air acoustic sensors. In Japan, Port and Airport Research Institute operates about 50 wave gauges outside ports and harbors (called NOWPHAS), using bottom acoustic sensors.

3.1.3 Pressure Gauges and Deep Ocean Measurements

In the deep ocean (near the tsunami source), tsunami waveforms are expected to be simpler and free from coastal topographic effects, although their amplitudes are smaller. Deep ocean measurements of tsunamis have been made in Japan and the United States using bottom pressure gauges for the purpose of early detection and warnings. The Japanese systems send signals through cables, while the US system uses acoustic modems and satellites. The latter data can be accessed at <http://www.pmel.noaa.gov/tsunami/>.

The quartz crystal pressure transducer is sensitive to changes corresponding to less than 1 mm of sea level change in the tsunami frequency band (Eble and Gonzalez, 1991). However, the pressure transducer is also very sensitive to temperature, hence the temperature correction is critical. Since the instrument is set on the ocean bottom, it also records ground motion and works as an ocean-bottom seismograph; seismic waves sometimes become noise for tsunami records (Okada, 1995).

3.2 Field Survey to Measure Run-up Heights

To supplement instrumental records, field surveys are carried out after large tsunamis. In the surveys, tsunami heights are estimated from various types of evidence, such as traces on walls, damage to constructions, scratches or dead leaves on trees, and seaweed or other floating materials transported by tsunamis (e.g., Hokkaido Tsunami Survey Group, 1993; Kawata *et al.*, 1999). Interviews with local people provide information on tsunami heights, though these are often subjective and less accurate. Interviewers also request the times of earthquake and tsunami, seismic intensity, and other descriptions of tsunamis.

3.3 Study of Historical Documents

Tsunamis and their damage recorded in historical documents are also useful in the study of old earthquakes and tsunamis for which no instrumental data are available. Some countries, such as Japan or Italy, have long histories of written records that have provided accurate dates for past earthquakes and tsunamis

(e.g., Tinti *et al.*, 1997). The long-term seismicity or recurrence interval of earthquakes and tsunamis can be studied from these records. The historical tsunami records could be also used for trans-Pacific tsunamis; the date of the most recent great earthquake in the Cascadia subduction zone was found to be 26 January 1700 from Japanese historical documents (Satake *et al.*, 1996).

3.4 Geological Methods

Even older tsunamis can be studied from their deposits by geological means. Geological studies of tsunami deposits have become popular in the last decade or so, and many examples, not only from earthquake-generated tsunamis but also from submarine landslides or impact-generated tsunamis, are reported. In Japan, Minoura and Nakaya (1991) examined the deposits from the 1983 Japan Sea tsunamis by drilling boreholes in lagoons. They further studied paleotsunamis through sedimentological and geochemical analyses, and estimated the dates and run-up heights of prehistoric tsunamis. In Europe, tsunami deposits from the Storegga slides in the North Sea have been found and carefully studied in Scotland, Norway, and Iceland (Dawson, 1994). In the United States, tsunami deposits from prehistoric great earthquakes along the Cascadia subduction zone have been studied (Atwater *et al.*, 1995; Clague, 1997). Geological evidence of late Pleistocene tsunamis has also been studied in Australia (e.g., Bryant *et al.*, 1996).

3.5 Definitions of Tsunami Heights and Sea Levels

3.5.1 Amplitude and Wave Heights

The *amplitude* is measured from zero to peak, either positive or negative. The *wave height*, also called range or double amplitude, is measured from trough to peak. Hence the *tsunami height* is measured from trough to peak on tide gauges, while the *tsunami amplitude* is measured from estimated tidal level at the time (Fig. 4).

3.5.2 Inundation and Run-up Heights

If no tide gauge record is available, the tsunami heights are measured by field surveys. The tsunami height on land measured from sea level at the time of tsunami arrival is called *inundation height*. The horizontal distance measured from the coast (at the time of tsunami arrival) is called *inundation distance*. Tsunami *run-up height* usually refers to the inundation height at the maximum inundation distance. The run-up height is not necessarily the same as the inundation height near the shore.

3.5.3 Sea Levels and Shoreline Problem

Several reference levels are used for measurements of water height or depth. *Mean sea level* is the average value of sea

FIGURE 4 Tide gauge record at Miyako, Japan, from the 1960 Chilean earthquake tsunami. The earthquake origin time was about 04:00 on 23 May on Japan Standard Time (JST), hence the travel times is nearly 23 h. Definitions of tsunami amplitude and wave height are also shown.

levels observed over a period of years, and is used as a reference level for geodetic surveys. On the other hand, hydrographical measurements, mostly water depth, are referenced to an extreme low water *Chart Datum*. It is *Mean Lower Low Water* in the United States, while it is *Lowest Low Water* in Japan. Hence there is a gap between the geodetic and hydrographic zero lines, known as the “shoreline problem.”

4. Hydrodynamics of Tsunamis

4.1 Shallow-Water (Long) Wave Theory

In this section, we take a two-dimensional Cartesian coordinate system with z axis vertical upward (the origin is on the undisturbed water level) and consider propagation of a wave (Fig. 5). When gravity is the restoring force, it is called a gravity wave. Euler’s equation of motion can be written as

$$\frac{D\mathbf{V}}{Dt} = -\mathbf{g} - \frac{1}{\rho}\nabla p \quad (6)$$

FIGURE 5 Coordinate system and important parameters for hydrodynamic computations of tsunamis (top). The lower figures schematically compare the shallow-water (long) waves and deep-water (short) waves. Particle motions are also shown.

where $\mathbf{V}$ is the velocity vector (whose x and z components are u and w , respectively), $\mathbf{g}$ is the gravitational acceleration, ρ and p are water density and pressure, respectively, and D/Dt indicates the total derivative

$$\frac{D\mathbf{V}}{Dt} = \frac{\partial \mathbf{V}}{\partial t} + \mathbf{V} \cdot \nabla \mathbf{V}$$

When the horizontal scale of motion, or the wavelength λ , is much larger than the water depth ($\lambda \gg d$), the vertical acceleration of water is negligible compared to gravity. This means that the horizontal motion of water mass is almost uniform from bottom to surface. Such a wave is called a shallow-water wave or long wave. For tsunamis, typical ocean depth is about 5 km and a large earthquake has a source size of several tens to hundreds of kilometers, hence the long-wave approximation is appropriate for most cases.

The horizontal component of expression (6) becomes, by replacing the horizontal pressure gradient with the slope of

water surface,

$$\frac{Du}{Dt} = -g \frac{\partial h}{\partial x} \quad (7)$$

For tsunamis, the nonlinear advective term is usually small and can be ignored,

$$\frac{Du}{Dt} = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} \approx \frac{\partial u}{\partial t}$$

Thus the equation of motion can be written as

$$\frac{\partial u}{\partial t} = -g \frac{\partial h}{\partial x} \quad (8)$$

When the amplitude is small compared to the water depth ($h \ll d$), the conservation of mass, or the equation of continuity, can be written as

$$\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x}(du) \quad (9)$$

Such a wave is called a small-amplitude, linear long wave. The assumptions are valid for most tsunami propagation paths except for near-shore regions.

From Eqs. (8) and (9), by assuming that water depth d is constant, we obtain the wave equation

$$\frac{\partial^2 h}{\partial t^2} = c^2 \frac{\partial^2 h}{\partial x^2} \quad \text{where} \quad c = \sqrt{gd} \quad (10)$$

in which the velocity is determined by the water depth only.

4.2 General Gravity Waves

We consider a general gravity wave travelling in the x direction, $h = a \cos(kx - \omega t)$, where a is amplitude, k is wavenumber, and ω is angular frequency. The phase velocity is given as

$$c = \frac{\omega}{k} = \left(\frac{g}{k} \tanh kd \right)^{1/2} = \left(\frac{g\lambda}{2\pi} \tanh \frac{2\pi d}{\lambda} \right)^{1/2} \quad (11)$$

and the horizontal and vertical particle velocities are given as follows

$$u = a\omega \frac{\cosh(k(z+d))}{\sinh kd} \cos(kx - \omega t) \quad (12)$$

$$w = a\omega \frac{\sinh(k(z+d))}{\sinh kd} \sin(kx - \omega t) \quad (13)$$

4.2.1 Shallow-Water (Long) Wave Approximation

When the water depth is much smaller than the wavelength ($d \ll \lambda$), we can approximate $\tanh(2\pi d/\lambda) \approx 2\pi d/\lambda$, $\sinh(2\pi d/\lambda) \approx 2\pi d/\lambda$, and $\cosh k(z+d) \approx \cosh kd \approx 1$. Then Eq. (11) becomes $c = \sqrt{gd}$, the long-wave approximation discussed

in the previous section. The vertical velocity [Eq. (13)] becomes

$$w = a\omega \left(1 + \frac{z}{d}\right) \sin(kx - \omega t) \quad (14)$$

which shows that $w = 0$ at the bottom, and w increases linearly toward the surface. The horizontal velocity [Eq. (12)] becomes

$$u = \frac{a\omega}{kd} \cos(kx - \omega t) = \frac{h\omega}{kd} \quad (15)$$

and the velocity ratio of vertical to horizontal components becomes $|w|/|u| = 2\pi d/\lambda$, which is very small. In other words, the particle motion is almost horizontal (Fig. 5).

4.2.2 Deep-Water (Short) Wave Approximation

When the water depth is much larger than the wavelength ($d \gg \lambda$), we can approximate

$$\tanh \frac{2\pi d}{\lambda} \approx 1$$

$$\cosh k(z+d) = \frac{1}{2}(e^{k(z+d)} + e^{-k(z+d)}) \approx \frac{1}{2}e^{k(z+d)}$$

and

$$\sinh kd = \frac{1}{2}(e^{kd} - e^{-kd}) \approx \frac{1}{2}e^{kd}$$

Then Eqs. (11) through (13) become

$$c = \frac{\omega}{k} = \left(\frac{g}{k} \right)^{1/2} = \left(\frac{g\lambda}{2\pi} \right)^{1/2} \quad (16)$$

$$u = a\omega e^{kz} \cos(kx - \omega t) \quad (17)$$

$$w = a\omega e^{kz} \sin(kx - \omega t) \quad (18)$$

These show that the particle motion is circular, and the amplitude decays exponentially with depth (Fig. 5). This is a surface wave. The phase velocity [Eq. (16)] shows a normal dispersion; the phase velocity is larger for longer wavelengths.

5. Tsunami Propagation

5.1 Ray Theoretical Approach

If the tsunami wavelength is much smaller than the scale of velocity heterogeneity, i.e., the depth change, then we can apply the geometrical ray theory of optics. The wavefronts can be drawn from raytracing results by connecting the locations of rays at the constant travel times. Such a diagram is called a *refraction diagram*. Traditionally, refraction diagrams have been drawn manually. Refraction diagrams can be prepared for major tsunami sources and used for tsunami warning; as soon as

FIGURE 6 Refraction diagram for the 1960 Chilean tsunami. Wavefronts at each hour after the earthquake are shown by curves.

the epicenter is known, the arrival time of tsunamis can be estimated from refraction diagrams.

Figure 6 shows the refraction diagram from the 1960 Chilean earthquake with wavefronts at each hour. It is shown that the tsunami was expected to arrive at Japan in about 23 h and the energy is focused because of refraction.

The refraction diagrams can also be drawn backward from coasts. Such a diagram is called an *inverse refraction diagram* and is used to estimate the tsunami source area; the wavefronts or rays can be traced backward for corresponding travel times. The traced wavefronts from each observed station bound the tsunami source area (see Section 6.4).

5.2 Green's Law

From the conservation of energy along the rays, we can obtain $b_0 d_0^{1/2} h_0^2 = b_1 d_1^{1/2} h_1^2$ where d is the water depth, b is the distance between the rays, h is the tsunami amplitude, and the subscripts 0 and 1 indicate two different locations. If the tsunami amplitude at location 0 (e.g., at the source) is known, the tsunami amplitude after the propagation can be estimated as

$$h_1 = \left(\frac{b_0}{b_1}\right)^{1/2} \left(\frac{d_0}{d_1}\right)^{1/4} h_0 \quad (19)$$

This is known as Green's law. The ratio b_1/b_0 represents the spreading of rays, which can be obtained graphically from refraction diagrams. Note that the amplitude at the coast must be that of the direct wave not of the reflected waves.

5.3 General Gravity Waves

Here we will briefly examine general gravity waves deviating from the small-amplitude, linear shallow-water (long) wave approximations. We have already seen that the phase velocity

of a gravity wave is given by Eq. (11). If we expand the hyperbolic tangent function into its Taylor series and include the second term, Eq. (11) becomes

$$c = \sqrt{gd} \left[1 - \frac{1}{3}(kd)^2\right]^{1/2} \approx \sqrt{gd} \left[1 - \frac{1}{6}(kd)^2\right] \quad (20)$$

The corresponding equation of motion is

$$\frac{\partial u}{\partial t} = -g \frac{\partial h}{\partial x} + \frac{1}{3} d^2 \frac{\partial^3 u}{\partial x^2 \partial t} \quad (21)$$

which is known as the linear Boussinesq equation.

If we relax the small-amplitude ($h \ll d$) assumption, the equations of motion and continuity are given as

$$\begin{aligned} \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} &= -g \frac{\partial h}{\partial x} \\ \frac{\partial h}{\partial t} &= -\frac{\partial}{\partial x} [u(h+d)] \end{aligned} \quad (22)$$

These equations are for the finite-amplitude shallow-water waves. For the linear case (ignoring the advection term), the phase velocity is given by $c = \sqrt{g(d+h)}$. This means that the larger the amplitude, the faster the wave speed. As a consequence, peaks of a wave catch up with troughs in front of them, and the forward-facing portion of the wave continues to steepen. It will then eventually break. Such a phenomenon is sometimes called *amplitude dispersion*.

5.4 Shallow-Water Wave Equations

Including the bottom friction and the Coriolis force, the equation of motion for shallow-water (long) waves can be written for a three-dimensional case as follows:

$$\begin{aligned} \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} &= -fV - g \frac{\partial h}{\partial x} - C_f \frac{U\sqrt{U^2 + V^2}}{d+h} \\ \frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} &= fU - g \frac{\partial h}{\partial y} - C_f \frac{V\sqrt{U^2 + V^2}}{d+h} \end{aligned} \quad (23)$$

and the equation of continuity is

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x} [U(h+d)] + \frac{\partial}{\partial y} [V(h+d)] = 0 \quad (24)$$

where the coordinate system is x =East and y =South, f is the Coriolis parameter, C_f is a nondimensional frictional coefficient, and U and V are the average velocities in the x and y directions, respectively. The velocities are averaged from the bottom to the surface,

$$\begin{aligned} U &= \frac{1}{(h+d)} \int_{-d}^h u dz = \frac{Q_x}{(h+d)} \\ V &= \frac{1}{(h+d)} \int_{-d}^h v dz = \frac{Q_y}{(h+d)} \end{aligned} \quad (25)$$

where Q_x and Q_y are flow rates in the x and y directions. A typical value of a nondimensional frictional coefficient C_f is 10^{-3} for coastal water and 10^{-2} for run-up on land (see, e.g., Satake, 1995).

5.5 Numerical Computations

Let us consider a simple one-dimensional propagation (on constant depth) of small-amplitude linear long waves. Denoting the average velocity (x component only) as U , the equations of motion and continuity are given as follows:

$$\frac{\partial U}{\partial t} = -g \frac{\partial h}{\partial x} \quad (26)$$

$$\frac{\partial h}{\partial t} = -d \frac{\partial U}{\partial x} \quad (27)$$

Using the staggered (leap-frog) grid system for U and h , and denoting time $t = l \Delta t$ as superscripts and space $x = m \Delta x$ as subscripts where l and m are integers, these become

$$\frac{[U_{m+\frac{1}{2}}^{l+\frac{1}{2}} - U_{m+\frac{1}{2}}^{l-\frac{1}{2}}]}{\Delta t} = -g \frac{[h_{m+1}^l - h_{m-1}^l]}{\Delta x} \quad (28)$$

$$\frac{[h_{m+\frac{1}{2}}^{l+1} - h_{m+\frac{1}{2}}^l]}{\Delta t} = -d \frac{[U_{m+1}^{l+\frac{1}{2}} - U_m^{l+\frac{1}{2}}]}{\Delta x} \quad (29)$$

It can be shown that the error will grow with time unless the following stability condition is met,

$$\sqrt{gd} \left(\frac{\Delta t}{\Delta x} \right) \leq 1 \quad \text{or} \quad \Delta t \leq \frac{\Delta x}{\sqrt{gd}}$$

which is known as the Courant–Friedrichs–Lewy (CFL) condition. The physical meaning of the stability condition is that the time step Δt must be equal to or smaller than the time required for the disturbance to travel the spatial grid size Δx . If Δt is larger, the values other than $(l, m-1)$, $(l-1, m)$, and $(l, m+1)$ will influence the value at $(l+1, m)$. For the two-dimensional case (Fig. 7), the CFL condition becomes

$$\Delta t \leq \frac{\Delta x}{\sqrt{2gd}} \quad (30)$$

There are two types of boundaries involved in the tsunami computation. The first is land–ocean boundary. The simplest assumption is a total reflection of energy on the coast. The other kind of boundary is the open boundary to outside the computational region. A typical assumption is the radiation condition, which means that waves go out of the computational region keeping their slopes.

The computer program for one-dimensional finite-difference computation is very simple. Since there is no overlap between the two (height and velocity) grids, in the program the spatial grid points m and $m + \frac{1}{2}$ can be treated by the

FIGURE 7 Typical staggered grid system used for two-dimensional finite-difference computation of tsunamis.

same argument (e.g., i) and the time $l - \frac{1}{2}$ and l can be treated as the same time (e.g., it). Writing U and h using the two-dimensional array as $U(i, it)$ and $h(i, it)$, Eqs. (28) and (29) become

$$U(i, 2) = U(i, 1) - g \frac{\Delta t}{\Delta x} [h(i, 1) - h(i-1, 1)]$$

$$h(i, 2) = h(i, 1) - d \frac{\Delta t}{\Delta x} [U(i+1, 2) - U(i, 2)]$$

The algorithm thus becomes as follows:

```

set up parameters
read bathymetry data
read initial condition h(i, 1)
while (it < it_end)
  compute U(i, 2) from U(i, 1) and h(i, 1)
  set U(i, 2) = 0 for land boundary
  compute h(i, 2) from U(i, 2) and h(i, 1)
  adjust h(i, 2) for open boundary
  exchange variables
    h(i, 2) -> h(i, 1)
    U(i, 2) -> U(i, 1)
  it += 1
end

```

6. Tsunami Generation by Earthquakes

6.1 Small Effect of the Earth–Ocean Coupling

The earthquake source is located in the elastic Earth, while a tsunami travels in the fluid ocean. Hence we need to first consider coupling between the elastic Earth and the ocean. In

the Earth–ocean coupled system, an earthquake source would generate “tsunami waves” both in the elastic Earth and in the ocean, and the propagation of a tsunami in the ocean layer might influence the elastic Earth. On the other hand, the traditional decoupled approach first calculates the elastic deformation on the ocean bottom generated by an earthquake, then uses this as an initial condition on the rigid ocean bottom; the tsunami wave in the ocean would have no influence on the elastic Earth. As we will see, because of the low compressibility of water, both approaches give almost identical solutions. In other words, the coupling between the elastic Earth and the ocean is extremely small, which explains why very large earthquakes are necessary to generate observable tsunamis.

Theoretical treatment of tsunamis is similar to that of Rayleigh waves or spheroidal oscillations. Yamashita and Sato (1974) formulated tsunami generation from a fault model and examined the effects of fault parameters on the tsunami amplitudes. Ward (1980) and Okal (1988) extended the free oscillation approach to solve the generation and propagation of tsunamis in the spherical coordinate system, while Comer (1984) extended the Rayleigh wave approach to solve them in

the Cartesian coordinate system. The phase velocity dispersion curve is shown in Figure 8. Except at very low frequencies, the phase velocity is very similar to that of the gravity wave (11), indicating that the coupling effect is negligibly small.

6.2 Ocean Bottom and Water Surface Displacements

Analytical solutions for linear gravity waves generated from several types of source have been obtained by various researchers. Kajiura (1963) generalized the solutions by introducing the Green’s functions. He showed that the initial conditions given at the ocean bottom and at the water surface differ by a factor of $1/\cosh kd$. As seen before, $\cosh kd = \cosh(2\pi d/\lambda) \approx 1$ if $\lambda \gg 2\pi d$. Therefore, if the wavelength of ocean bottom deformation is much larger than the water depth, it can be assumed that the water surface displacement is the same as the bottom displacement.

Kajiura (1970) examined the energy exchange between the solid Earth and ocean water for tsunamis generated by bottom deformation with finite rise time. He showed that the efficiency of tsunami generation, defined as a ratio of dynamic tsunami energy to static energy, becomes nearly unity if the duration is short compared to the time required for a tsunami to travel through the source area. For an earthquake with $M \sim 8$ at a water depth of 5000 m, the source size is about 100 km and the tsunami travel time over that distance is about 8 min. If the duration is much shorter, e.g., 1 min or less, the efficiency is more than 0.9. This means that the bottom deformation can be considered as instantaneous. If the duration is too short, shorter than $2\sqrt{d/g}$, a part of the energy flux goes into acoustic waves. For the above case, this limit is 45 sec.

FIGURE 8 Top: Schematic comparison of the coupled and decoupled systems. Bottom: The dispersion curves for the tsunami phase velocity computed for a 4000 m deep ocean. (Reproduced with permission from Comer, 1984.)

6.3 Fault Parameters and Ocean Bottom Deformation

The ocean bottom deformation due to faulting can be calculated using the elastic theory of dislocation. The displacement in an infinite homogeneous medium due to a dislocation across a fault is given by Volterra’s theorem (see, e.g., Steketee, 1958) and the explicit formulas are given in Okada (1985), for example. Usually, only the vertical component of the ocean bottom is considered for tsunami generation. When the tsunami source is on a steep ocean slope and the horizontal displacement is large, the vertical displacement of water due to the horizontal displacement of the slope must also be considered (Tanioka and Satake, 1996a).

The fault parameters needed to compute surface deformation are the fault location, geometry (strike, dip, and rake), size (length L and width W), and average slip $\bar{u}$ (or the strike-slip and dip-slip components). The seismic moment M_0 is given as

$$M_0 = \mu \bar{u} S = \mu \bar{u} L W \quad (31)$$

where S is the fault area and μ is rigidity. The moment magnitude is defined as

$$M_w = \frac{\log M_0 - 9.1}{1.5} \quad (32)$$

where M_0 is given in N m. The effects of fault parameters on tsunami generation were examined by Yamashita and Sato (1974) and more recently by Geist (1998).

6.4 Estimation of Earthquake Source Parameters from Tsunamis

Tsunami data can be used to study earthquake source processes in a way similar to that in which seismic waves are used. Abe (1973) analyzed the tsunami arrival times and first-motion data from the 1968 Tokachi-oki earthquake (Fig. 9). By drawing inverse refraction diagrams from each station, he estimated the tsunami source area, which agrees well with the aftershock area. From the first motion of tsunami waves, the initial water surface disturbance was estimated as uplift at the southeastern edge and subsidence at the northwestern edge. This pattern is very similar to the crustal deformation due to the faulting, which was independently estimated from seismological analysis.

Tsunami waveforms recorded on tide gauges can be inverted to estimate the slip distribution on the fault (Satake, 1989). In this method (Fig. 10), the fault plane is first divided into several subfaults and the deformation on the ocean bottom is computed for each subfault with a unit amount of slip. Using this as an initial condition, tsunami waveforms are numerically computed on actual bathymetry. The observed

tsunami waveforms are expressed as a superposition of the computed waveforms as follows,

$$A_{ij}(t) \cdot x_j = b_i(t) \quad (33)$$

where A_{ij} is the computed waveform, or Green's function, at the i th station from the j th subfault; x_j is the amount of

FIGURE 10 Schematic illustration of tsunami waveform inversion.

FIGURE 9 The tsunami source area and crustal deformation pattern of the 1968 Tokachi-oki earthquake. The left panel shows the distribution of tide gauge stations (with numbers) where the tsunami waveforms were recorded. The center panel shows the travel-time arcs for each tide gauge station. The attached numbers correspond to the station numbers in the left panel. Solid and dashed arcs represent positive and negative first arrivals. The right panel shows the ocean bottom deformation calculated from a fault model. (Reproduced with permission from Abe, 1973; copyright Elsevier Science Publishers.)

FIGURE 11 Comparison of the observed (solid) and computed (dashed) tsunami waveforms for the 1993 Southwest Hokkaido earthquake. The computation was made from a heterogeneous fault model obtained by the inversion of tsunami and geodetic data. The numbers below the tide gauge station names indicate the time range in minutes after the earthquake. (From Tanioka *et al.*, 1995; copyright American Geophysical Union.)

slip on the j th subfault; and b_i is the observed tsunami waveform at the i th station. The slip x_j on each subfault can be estimated by a least-squares inversion of the above set of equations. Figure 11 shows the comparison of observed and computed tsunami waveforms for the 1993 Southwest Hokkaido earthquake. Computed waveforms are very similar to the observed ones.

The tsunami waveform inversion has been applied to many large and great earthquakes in the Alaska-Aleutians (e.g., Johnson, 1998), northern Japan (e.g., Satake, 1989; Tanioka *et al.*, 1995), and the Nankai trough (Satake, 1993), among others. These results show that the slip distributions are not uniform but are concentrated in small regions that correspond to asperities.

6.5 Tsunami Earthquakes

A “tsunami earthquake” is defined as an earthquake that excites much larger tsunamis than expected from its seismic

waves (Kanamori, 1972). The discrepancy can be quantified in terms of the surface wave magnitude (M_S) and tsunami magnitude (M_t) scales; when M_t is larger than M_S by more than 0.5 units, it is called a tsunami earthquake (Abe, 1989; see Fig. 2).

Several proposals have been made for the generating mechanisms. Kanamori (1972) indicated that the large discrepancy between seismic and tsunami waves can be explained by a slow and long rupture process. Fukao (1979) explained the large tsunami excitation by slips in the accretionary wedge. A high-angle subsidiary fault in the wedge may cause a significant tsunami, but contribution to the seismic moment may be small because of low rigidity. Pelayo and Wiens (1992) showed that the tsunami heights were not anomalously large if compared to the seismic moments; the large discrepancy between the tsunami and M_S is due to a saturation of M_S at around 7.3 for those earthquakes that occurred in the accretionary wedge. Okal (1988), using the normal-mode theory, showed that an earthquake source in

a shallow sedimentary layer can excite much larger tsunamis than in solid rock for certain geometries.

Recent tsunami waveform modeling shows that the fault parameters and locations of tsunami earthquakes share a common feature: narrow and shallow faulting near the trench axis (Satake and Tanioka, 1999; Fig. 12). The 1992 Nicaragua earthquake ($M_S = 7.2$, $M_t = 7.9$) was the first tsunami earthquake recorded on modern broadband seismic instruments, and seismological studies showed that the duration was very long for its size, about 100 sec (Kanamori and Kikuchi, 1993). Satake (1994) compared the numerically computed tsunami waveforms with tide gauge records and showed that a narrow (~ 40 km) and shallow (extending only to the upper 10 km of the ocean bottom) fault was responsible for the tsunami generation. A similar feature was found for other tsunami earthquakes: the 1946 Aleutian earthquake ($M_S = 7.3$, $M_t = 9.3$; Johnson and Satake, 1997) and the 1896 Sanriku earthquake ($M_S = 7.2$, $M_t = 8.6$; Tanioka and Satake, 1996b). The large tsunami excitation is attributed to a slow rupture, presumably within the shallow subducted sediments. Tanioka *et al.* (1997) showed that the surface roughness of the ocean bottom near the trench is well correlated with the large earthquake occurrence. The 1896 tsunami earthquake occurred in a region where the ocean bottom topography is rough, characterized by well-developed horst and graben structure.

7. Tsunami Warning Systems

Tsunamis travel very fast as ocean waves, about 800 km h^{-1} , or 0.2 km sec^{-1} , for a water depth of 5000 m, but they are still much slower than seismic waves. This velocity difference between the seismic and tsunami waves makes it possible to issue a tsunami warning after seismic wave detection but before the arrival of the tsunami.

Current tsunami warning systems can be grouped into a Pacific-wide system and regional (or local) systems. The Pacific Tsunami Warning Center located in Hawaii monitors seismic and tsunami waves, issues tsunami warnings, and communicates with foreign agencies for the Pacific-wide tsunamis. It takes at least several hours for a tsunami to travel across the Pacific Ocean, so that a tsunami warning can be issued after the tsunami is actually detected somewhere and it is confirmed that it is dangerous.

The French Polynesia Tsunami Warning Center developed and adopted TREMORS (Tsunami Risk Evaluation through seismic MOment in a Real-time System) in 1987 (Reymond *et al.*, 1991). TREMORS features automatic detection and location of earthquakes using a single three-component long-period seismic station, and estimation of seismic moment through variable-period mantle magnitude, M_m (Okal and Talandier, 1989). The advantage of using long-period seismic waves for tsunami warning is the ability to estimate the overall

FIGURE 12 Schematic view of the source regions (bottom) and vertical deformation on ocean bottom (top) for typical interplate (left) and tsunami (right) earthquakes. The source region of an interplate earthquake typically extends from a depth of 10–40 km. The ocean bottom above the source region is uplifted and becomes the tsunami source. The source region of a tsunami earthquake is at shallower extension near the trench axis.

FIGURE 13 Flow diagram of the Tsunami Warning Center system employed at the Japan Meteorological Agency.

size of large or great earthquakes, and the possibility of detecting “tsunami earthquakes” (e.g., Newman and Okal, 1998), but the disadvantage is that longer time is needed before the seismic waves are recorded. TREMORS is a hybrid system; it updates the moment estimate as more seismic data are available.

In the case of regional and local tsunami warnings, a tsunami warning must be issued immediately after the occurrence of an earthquake, because time before the tsunami arrival is shorter—on the order of minutes. Japan Meteorological Agency (JMA) operates a nationwide seismic observation system and has six Regional Tsunami Warning Centers where seismologists are on duty 24 h a day (Fig. 13). When a large earthquake occurs, one of four messages (Major Tsunami, Tsunami, Tsunami Attention, or No Tsunami) is issued for each coastal region, based on the magnitude, location, and depth of the earthquake, and the distance to each coastal region. JMA quickly issues earthquake information (region and intensity, without location or magnitude) within 2 min of an earthquake, followed by a tsunami warning within a minute. The recent warnings include tsunami arrival times and heights estimated from pre-made numerical computations. Several thousands of numerical computations have been used to construct the database (Tatehata, 1997).

Geology of the Crustal Earthquake Source

Richard H. Sibson

University of Otago, Dunedin, New Zealand

1. Introduction

Earthquakes occur in rock, and rocks of many different kinds provide important information on earthquake processes. The specific focus here is on shallow crustal earthquakes responsible for the vast bulk of earthquake damage; subduction-related events are not discussed to any extent. Primary earthquake effects—incremental fault slip, shaking (strong ground motion), and abrupt changes in the tectonic stress state (including shear stress, τ , mean stress, $\bar{\sigma}$, and fluid-pressure, P_f)—affect many fundamental geological processes (Fig. 1). Earthquake effects are thus widely recorded in rocks, though deciphering the seismological significance of this geological information is in its infancy. However, paleoseismic studies—interpreting the Holocene sedimentary and geomorphic record in terms of seismic increments of fault slip—have made enormous advances in recent years (McCalpin, 1996). These aspects of *earthquake geology* of special relevance to seismic hazard assessment are treated separately in Chapters 30 by Grant and 31 by Jackson.

FIGURE 1 Earthquake geology—the involvement of primary earthquake effects (fault slip, shaking, and stress change) in geologic processes.

This chapter focuses specifically on the geological structure and rheology of crustal fault zones in relation to the mechanics of shallow earthquakes.

2. Faulting in Seismogenic Crust

Crustal earthquake activity is concentrated at plate boundaries in association with large, fast-moving fault systems but also occurs, sporadically, far from plate margins, especially in continental intraplate regions which may possess a variety of structures inherited from former tectonic episodes.

2.1 Fault Activity and Slip Modes

The degree of activity on a fault can be classified in terms of the time-averaged slip-rate (v_{ta}) across the structure established from the Holocene (<10 ka) or Quaternary (<1.8 Ma) geologic record (Matsuda, 1975) (Table 1). Plate boundary fault systems tend to be dominated by an isolated Class AA fault and/or a mesh of Class A structures within a hierarchy of still-slower moving faults. As a general rule, intraplate earthquakes occur on far slower moving faults (Class A or less).

Fault creep, though widespread within the San Andreas strike-slip fault system of California where it is accompanied by high levels of microseismic activity (Burford and Harsh, 1980; Hill *et al.*, 1990), is comparatively rare on a global scale (aside from postseismic afterslip) with the exception of some

TABLE 1 Fault Slip-Rate and Earthquake Recurrence

Class	v_{ta} (mm y^{-1})	R.I. (years)	
		($\bar{u} = 1$ m)	($\bar{u} = 10$ m)
AA	>10	<100	<1000
A	$1-10$	$100-1000$	$1000-10\,000$
B	$0.1-1.0$	$1000-10\,000$	$10\,000-100\,000$
C	$0.01-0.1$	$10\,000-100\,000$	$100\,000-1\,000\,000$

subduction boundaries. At least onshore, seismic rupturing appears to be the dominant mode of fault slip in the upper crust. Recurrence intervals between successive earthquakes with a characteristic slip value, $\bar{u}$, are then simply anticipated through the recurrence equation:

$$\text{R.I.} = \bar{u}/v_{\text{ta}} \quad (1)$$

suggested by Wallace (1970), though there is no a priori reason why v_{ta} must remain constant over long time periods. Expected recurrence intervals between successive large earthquakes ($1 < \bar{u} < 10$ m) on faults with varying activity levels are given in Table 1.

2.2 Seismogenic Crust

Away from areas of active subduction where thermal and fluid-pressure regimes are severely perturbed, the vast bulk of earthquake activity is restricted to the Earth's crust and, in continental regions, mostly to within the upper half of the crust (Meissner and Strehlau, 1982; Sibson, 1982; Chen and Molnar, 1983).

2.2.1 Continental Seismogenic Zone

In areas of moderate to high heat flow ($60\text{--}100\text{ mW m}^{-2}$) within deforming continental crust, microearthquake activity is largely confined to the top 10–20 km of the crust (e.g., Hill *et al.*, 1990). Activity shallows to depths of ~ 5 km in areas of intense geothermal activity and, though more diffuse, deepens to depths of ~ 25 km in colder cratonic crust as in eastern North America. Temperatures at the continental seismic–aseismic transition are inferred to vary from $\sim 300^\circ\text{C}$ to $\sim 450^\circ\text{C}$ for, respectively, quartz-dominant and feldspar-dominant rheologies (Sibson, 1984; Scholz, 1988). A notable feature is that larger earthquakes ($M > 6$) tend to nucleate toward the bottom of this microseismically defined seismogenic zone (Fig. 2); it

seems likely that larger ruptures occasionally penetrate downwards some distance below the background seismogenic zone (Strehlau, 1986). Minor seismic activity also occurs within the upper mantle below an aseismic lower crust in some areas of continental convergence (Chen and Molnar, 1983).

Similar correlations between regional heat flow and the thickness of the seismogenic zone have been noted in southwest Japan (Ito, 1999), with a temperature of $350 \pm 50^\circ\text{C}$ inferred for the base of the seismogenic zone. Moreover, drilling into the contact aureole to a Late Quaternary granitic pluton ($T > 500^\circ\text{C}$) within the Kakkonda geothermal field, northeast Japan, has allowed direct correlation of the local microseismicity cut-out at ~ 2 km depth with the 350°C isotherm (Muraoka *et al.*, 1998). Also in northeast Japan, high resolution studies have revealed a particularly sharp transition between “standard” upper crustal seismicity in the deforming arc and that associated with the subduction interface and downgoing subducted slab (Hasegawa *et al.*, 1994).

2.2.2 Oceanic Seismogenic Zone

In oceanic areas away from spreading ridges it is apparent that both microearthquake activity (e.g., Shen *et al.*, 1997) and large events (Anderson and Zhang, 1991) can nucleate below the crust and propagate through the oceanic lithosphere. The depth of intraplate earthquakes in the oceans appears to be governed by olivine rheology and extends down to temperatures as high as $\sim 750^\circ\text{C}$, but along major transform faults the depth of rupturing is significantly shallower, corresponding to temperatures in the range of $400\text{--}600^\circ\text{C}$ (Engeln *et al.*, 1986).

2.2.3 Varying Seismic Style

Moderate-to-large tectonic earthquakes generally occur as mainshock–aftershock sequences, sometimes with premonitory foreshocks. Studies of moment release and surface

FIGURE 2 Strike-parallel longitudinal section illustrating varying seismic style along a major strike-slip fault zone (modeled on the San Andreas fault) and the relationship of small and large ruptures (perimeters defined by aftershock concentrations-filled circles) to the continental seismogenic zone defined by background microseismicity (open circles).

fault-breaks, coupled with geodetic analyses and precision aftershock locations, suggest that the bulk of slip during rupture is usually confined to a thin tabular zone of indeterminate thickness, though aftershock activity may be distributed through substantial volumes of rock, especially near rupture irregularities. Scholz (1982, 1997) argues that the typical 10–20 km thickness of the seismogenic zone imposes a fundamental length scale on crustal rupturing (Fig. 2). “Small” ruptures confined within the seismogenic layer follow different scaling laws from “large” earthquakes ($M > 6$) that rupture the full depth of the seismogenic zone and then extend along strike to rupture lengths that may be many times the seismogenic thickness (Pacheco *et al.*, 1992).

Earthquake swarms are a variant of seismic activity where numerous small earthquakes occur without a distinct principal shock, the activity waxing and waning through time and sometimes migrating. A key distinction from standard tectonic earthquakes is that swarms tend to be distributed throughout a substantial volume of rock. They are frequently associated with areas of recent volcanic or geothermal activity within extensional and transtensional tectonic regimes; in the latter, swarms are often localized within dilational stepovers. To account for swarm characteristics, Hill (1977) proposed a mechanical model involving migration of magmatic fluids through a “honeycomb” mesh of interlinked minor shear and extension fractures (Fig. 3). Such interlinked fault-fracture meshes can be recognized in rocks on a variety of scales,

FIGURE 3 Mesh model for swarm seismicity involving interlinked minor faults and extension fractures infilled with dikes, hydrothermal veins, etc. (cross-hatched) developed in relation to principal compressive stresses, $\sigma_1 > \sigma_2 > \sigma_3$ (after Hill, 1977).

functioning as migratory conduits for hydrothermal and hydrocarbon, as well as magmatic fluids (Sibson, 1996).

Major fault zones such as the San Andreas fault system also exhibit significant along-strike variations in seismic style (Wallace, 1970; Hill *et al.*, 1990). Microseismic activity is extremely low along the two segments of the San Andreas Fault which ruptured historically in great $M \sim 8$ earthquakes in 1857 and 1906. In contrast, along segments of the San Andreas and Calaveras faults which are actively creeping, the fault zone is defined by clustered microearthquakes as a subvertical tabular structure extending through most of the seismogenic zone (Fig. 2). Indications from paleoseismology are that these variations in current seismic style represent long-term characteristics of San Andreas fault behavior.

3. Internal Structure and Rheology of Crustal Fault Zones

Surface and mine exposures of ancient fault systems exhumed from different depths provide information on the internal structure, slip processes, and rheology of fault zones at different levels in the crust.

3.1 General Model of a Transcrustal Fault Zone

Major transcrustal fault zones appear as predominantly tabular features in both brittle and ductile regions of the crust with some evidence of flaring with increasing depth in the middle to lower crust (Hanmer, 1988). Their internal structure is often highly heterogeneous with slip and/or strain localized on principal displacement zones (PDZ) which may be planar over considerable distances or anastomose in a mesh-like structure (Wallace and Morris, 1986). In the brittle upper crust, PDZ are commonly localized within or, commonly, at one or other margin to a fault zone of varying thickness ($< \sim 1$ km for large-displacement strike-slip faults) comprising variably fractured and cataclastically deformed material. In the ductile middle to lower crust, high-strain shear zones anastomose around lozenges of comparatively low-strain material. Syntectonic hydrothermal veining may be variably developed at all crustal levels.

3.1.1 Fault Rock Distribution

Fault rocks (reduced in grain size from their protoliths by a range of mechanisms) exhibit a wide variety of microstructural characteristics determined by their parent rock, their original deformation environment, and their exhumation path (Snoke *et al.*, 1998). Their distribution in and around ancient fault zones has been used to build conceptual models of transcrustal fault zones, mostly for quartzofeldspathic continental crust (Sibson, 1977, 1983; Hanmer, 1988; Passchier and Trouw, 1996). For monolithologic crust, a general depth progression

in the predominant fault rock type:

gouge/breccia → *cataclasite* → *mylonite* → *mylonitic gneiss*
(often clay-rich)

has been established but it should be noted that geobarometric controls are generally poor. The effect of crustal heterogeneity flanking a transcrustal fault zone is to smear-out this dominant fault-rock progression, forming a *mélange* of competent and incompetent material (Fig. 4).

3.1.1.1 Frictional Regime (FR)

Incohesive gouge and breccia, and cohesive rocks of the cataclasite series (with increasing grain refinement, *protocataclasite* → *cataclasite* → *ultracataclasite*) have deformed largely by brittle cataclastic processes accompanied by varying amounts of hydrothermal alteration. Textures range from essentially random-fabric to foliated with alignment of elongate clasts defining shape fabrics. Associated minor structures include Riedel shear arrays (Tchalenko, 1970; Rutter *et al.*, 1986), and local hydrothermal veining hosted by shear and

extension fractures. Discrete slip surfaces may carry frictional striae and other wear-induced features or hydrothermal growth fibers (slickenfibers) indicating slip direction and shear-sense (Doblas, 1998). The predominant fault rocks associated with PDZ are ultracataclasites (Chester *et al.*, 1993). Associated sparse development of pseudotachylite friction-melt provides relic evidence of transient high power dissipation accompanying seismic slip (see Section 3.2.1) but in general, partly because of structural overprinting, distinguishing seismic from aseismic deformation features is problematic. Evidence for diffusive mass transfer (pressure solution) is sometimes present in finer grained cataclastic detritus with development of phyllonitic microstructure (Bos *et al.*, 2000) but the predominance of cataclastic processes suggests that shearing is governed by pressure-dependent frictional interaction at grain boundaries and along sliding surfaces.

3.1.1.2 Quasi-plastic Regime (QP)

A progressive transition in shearing processes occurs within continental fault zones near the onset of greenschist facies metamorphic conditions ($T > \sim 300^\circ\text{C}$), marked by the appearance of fault rocks of the mylonites series (*protomylonite* → *mylonite* → *ultramylonite*). Development of penetrative L–S mylonitic fabrics (penetrative foliation with stretch lineation) involves temperature-sensitive crystal plastic flow by dislocation creep which sets in for quartz at $T > 300\text{--}350^\circ\text{C}$ and for feldspar at $T > 450^\circ\text{C}$ (Simpson, 1985; Carter and Tsenn, 1987). Greenschist mylonitization therefore generally involves a mixture of deformation mechanisms with plastic flow of quartz accompanied by feldspar cataclasis. Crystal plastic flow may also be aided or supplanted by diffusional mechanisms as grain size is reduced by dynamic recrystallization and/or cataclasis (White *et al.*, 1980; Chester, 1995). As originally defined (Sibson, 1977), the quasi-plastic (QP) regime embraces all these flow mechanisms, with well-ordered mylonitic fabrics largely the product of aseismic shearing.

Textures of mylonitic gneisses (also predominantly L–S tectonites) developed under higher greenschist to amphibolite facies metamorphic conditions in the lower crust ($T > 500^\circ\text{C}$) record more continuous shearing deformation within ductile shear zones that commonly range from hundreds of meters to tens of kilometers in thickness (Hanmer, 1988; Corsini *et al.*, 1996).

3.1.1.3 Complexity of the FR/QP Transition

Inevitably, the change from frictional faulting to quasiplastic shearing is gradational across a substantial depth interval, with compositional heterogeneity contributing to the smearing-out of the transition. Fault-rock textures from this transitional region record a mixture of discontinuous and continuous shearing (for example, mylonitic fabrics interlaced with deformed pseudotachylites, cataclasites, or hydrothermal fault-veins, White, 1996; Takagi *et al.*, 2000). Moreover, once grain size has been reduced by cataclasis or dynamic recrystallization within the temperature range $200\text{--}400^\circ\text{C}$, hydrothermal

FIGURE 4 General rheological model and schematic strength profile for a transcrustal strike-slip fault zone under a geothermal gradient of $\sim 25^\circ\text{C km}^{-1}$. Frictional fault strength calculated assuming optimal orientation and hydrostatic fluid pressures (comparative strengths of optimal normal and reverse faults also shown). Average frictional strength imposed by heat flow constraint on the San Andreas fault shown for comparison.

alteration leads to reaction weakening and the development of phyllonites (hydrated phyllosilicate-rich mylonites) deforming in part by diffusional flow mechanisms (Chester, 1995). Indeed, on the basis of kaolinite–halite analog shearing experiments, Bos *et al.* (2000) suggest that a broad transitional regime may be characterized by mixed frictional–viscous behavior with strength reduced by up to a factor of 3. To complicate the situation further, hydrothermal vein systems provide evidence for substantial fluid-pressure cycling at this structural level in the crust (see Section 5.4.4; Robert *et al.*, 1995; Parry, 1998).

3.1.1.4 Hydrothermal Veining

Syntectonic hydrothermal veins (quartz, calcite, zeolites, etc.) are variably developed at different levels within crustal fault zones (see also Section 5.1). Hydrothermal material may infill breccias and irregular fractures, but may also occupy originally planar fractures in systematic vein-sets. These include fault-veins lying along shearing surfaces and extension veins occupying purely extensional fractures. Both commonly have crystal growth textures recording incremental development. Macroscopic extension veins, usually interpreted as the product of natural hydraulic fracturing, have special significance in that they require fluid-pressure to have exceeded the least compressive stress (i.e., $P_f > \sigma_3$) with differential stress less than four times the tensile strength of the rock ($(\sigma_1 - \sigma_3) < 4T$) at the time of their formation (Secor, 1965). Tensile strengths for most sedimentary rocks are less than 10 MPa, and for crystalline rocks rarely exceed 20 MPa (Lockner, 1995). Thus, apart from indicating fluid overpressures in other-than near-surface conditions (see Section 5.3), the presence of extension veining puts an upper limit on differential stress in fault zones (Etheridge, 1983).

Hydrothermal cementation assisted by solution transfer within fine cataclastic detritus may also contribute to “fault-healing” through interseismic periods (Angevine *et al.*, 1982; and Chapter 32 by Lockner and Beeler).

3.1.2 Shear Strength Profiles

Given the field evidence on the changing rheology of a trans-crustal fault zone with depth, a simple procedure may be used to construct bounding profiles of shear resistance versus depth in the crust (Sibson, 1982, 1984; Smith and Bruhn, 1984). The procedure depends critically on input assumptions and, for a variety of reasons, the resulting profiles should generally be regarded as providing an upper limit to the shear strength of natural fault zones.

Shear resistance in the upper crustal frictional (FR) regime is estimated from Amontons Law:

$$\tau_{fr} = \mu_s \sigma_n' = \mu_s (\sigma_n - P_f) \quad (2)$$

where μ_s , the static coefficient of rock friction is generally assumed to lie within Byerlee’s (1978) experimentally

determined range ($0.6 < \mu_s < 0.85$), σ_n is the normal stress on the fault and P_f is the fluid pressure. Frictional shear resistance at a depth, z , can then be expressed as a function of the effective vertical stress:

$$\tau_{fr} = c \mu_s \sigma_v' = c \mu_s (\sigma_v - P_f) = c \mu_s \rho g z (1 - \lambda_v) \quad (3)$$

where c is a geometrical factor depending on fault attitude and the prevailing stress field, ρ is the average rock density, g is gravitational acceleration, and the pore-fluid factor, $\lambda_v = P_f/\sigma_v$. For the three basic stress regimes with $\sigma_v = \sigma_1$, σ_2 , or σ_3 (Anderson, 1951), and with a representative “Byerlee” friction coefficient, $\mu_s = 0.75$, $c = 0.40$, 0.64 , and 1.60 for normal, strike-slip, and thrust faults, respectively, when they are optimally oriented for frictional reactivation (containing σ_2 and lying at $\sim 27^\circ$ to σ_1) (Sibson, 1974). Profiles are usually constructed on the assumption of hydrostatic fluid pressures ($\lambda_v \sim 0.4$) throughout the frictional regime.

Support for this procedure comes from borehole measurements made to depths as great as 9 km in crystalline cratonic crust which reveal fluid-pressures close to hydrostatic, and stress levels generally consistent with critical stressing of optimally oriented faults with “Byerlee” friction coefficients (Townend and Zoback, 2000).

Flow shear resistance in the QP regime is generally assumed to be governed by a temperature-dependent power law appropriate to dislocation creep, of general form:

$$\tau_{fl} = [A \dot{\gamma} \exp(Q/RT)]^{(1/n)} \quad (4)$$

where $\dot{\gamma}$ is the shear strain-rate, Q is the activation energy, R is the gas constant, T is absolute temperature, and A and n are material constants derived from laboratory experiments (Carter and Tsenn, 1987). Estimates of flow strength at a particular depth, therefore, require specification of the geotherm and the strain-rate in the QP regime. For the commonly observed widths of ductile shear zones in the mid-crust, localized aseismic strain-rates in the range $10^{-13} < \dot{\gamma} < 10^{-10} \text{ sec}^{-1}$ seem appropriate.

Application of this procedure leads to acute peaks in shear strength and associated strain energy concentration at the FR/QP transition (Fig. 4). However, the limitations of the input assumptions should be kept in mind. For instance, many fault zones are oriented at other than optimal orientations for frictional reactivation (e.g., Fig. 6), leading to higher frictional strength. But frictional strength may be significantly lowered by a high phyllosilicate content in the fault zone (Bos *et al.*, 2000) or by fluid pressure levels elevated above hydrostatic (Streit, 1997). In the QP regime, extrapolation of flow laws derived from fast strain-rate, low-strain laboratory experiments to much slower, large-strain natural deformation is questionable. Complexities arise from the polyminerale character of fault-rock assemblages (Kawamoto and Shimamoto, 1998). Nor is any account usually taken of

diffusional mechanisms which may bring about significant strength reduction, especially in the 200–400°C temperature range embracing the FR/QP transition (Chester, 1995; Bos *et al.*, 2000).

3.1.3 Relationship to Seismogenic Zone

Commonly inferred temperatures at the base of the seismogenic zone in continental crust ($T = 350 \pm 50^\circ\text{C}$) accord with the recognition of a progressive transition from predominantly frictional (FR) to predominantly quasi-plastic (QP) deformation processes in fault zones (corresponding to the cataclasite–mylonite transition) at the onset of greenschist facies metamorphic conditions. Fault-zone rheology is strongly affected by the quartz/feldspar ratio: the temperature of the FR/QP transition can change from $T \sim 350^\circ\text{C}$ for quartz-rich material to $T \sim 450^\circ\text{C}$ where feldspar is the dominant load-bearing constituent within the rock-mass. Thus, crustal heterogeneity tends to smear out this complex transition zone involving a mixture of discontinuous and continuous shearing processes. Coupled with variations in regional heat flow, these factors account for much of the observed variation in the depth of the seismogenic zone (Sibson, 1984; Smith and Bruhn, 1984). Complexity at the base of the seismogenic zone, however, may be further compounded by fluid-pressure cycling in the vicinity of the FR/QP transition (Sibson, 1992, 1994).

The base of the seismogenic zone is also sometimes referred to as the brittle-plastic transition (e.g., Scholz, 1988, 1990), a not entirely appropriate term as it takes no account of the potential role played by diffusional flow mechanisms in fine-grained fault rocks. For example, Rutter and Brodie (1987) suggest that shallowing of seismic activity along transform faults in the oceanic lithosphere, in comparison with intraplate regions (Engeln *et al.*, 1986), may be governed by the dehydration of serpentinized ultramafics to a very fine-grained olivine, promoting weak aseismic shearing through grain boundary diffusion.

Another interpretation takes account of constitutive laws recently established for sliding friction in rocks (Dieterich, 1978; Blanpied *et al.*, 1995; Scholz, 1998). Frictional stick-slip instability believed responsible for shallow crustal earthquakes requires velocity-weakening behavior. Increasing temperature leads to velocity-strengthening and corresponds to a change from abrasive to adhesive wear, equated with the cataclasite–mylonite transition (Scholz, 1988, 1998). Marone and Scholz (1988) also suggest that the aseismic character of the upper 2–4 km of major fault zones such as the San Andreas results from velocity-strengthening behavior of unconsolidated granular material at low confining pressure. It is tempting to equate this zone to the anticipated transition from incohesive gouge-breccia (often clay-rich) in the top 3–4 km of mature fault zones to cohesive, well-compacted cataclasites (Fig. 4).

3.2 Seismic Slip Processes

For typical seismic slip-rates of $\sim 1 \text{ m sec}^{-1}$, power dissipated over a fault surface during rupture is of the order of 10–100 MW m^{-2} for frictional shear resistances, $\tau_{fr} = 10$ and 100 MPa, respectively. Such high power dissipation can lead to intense disordering, or, if shearing is restricted to a narrow zone, to large increases in temperature. Given the short time periods involved (rise times of 1–10 sec), heating is essentially adiabatic for slip zones thicker than about 10 mm and temperature increase is approximated by:

$$\Delta T = \frac{\tau_{fr} u}{c_p \rho s} \quad (5)$$

where u is the coseismic slip, s is the thickness of the seismogenic shear zone, ρ is rock density, and the specific heat, $c_p \sim 1000 \text{ J kg}^{-1}^\circ\text{C}$ for most rocks. Anticipated temperature increases are plotted against shear zone thickness, s , for coseismic displacements of 0.1, 1, 5, and 10 m against constant shear resistances of 10 and 100 MPa (Fig. 5a).

For displacement accompanying moderate to large earthquakes (1–5 m) temperature increases of around 1000°C would be expected for $\tau_{fr} = 100 \text{ MPa}$, provided slip is confined to a zone less than 0.1–0.2 m in thickness, or less than 10–20 mm if $\tau_{fr} = 10 \text{ MPa}$. Temperature rises of $\sim 100^\circ\text{C}$ can be expected for slip zones that are an order of magnitude thicker. Geologically based estimates of the thickness of the seismogenic slip zone, along with crude estimates of applicable depths, are given in Figure 5b. Most suggest that seismic slip on PDZ is commonly localized to within less than 0.1 m, and often to less than 10 mm.

Given the likelihood of significant temperature increase during a seismic slip increment, shear resistance is unlikely to stay constant during rupture. Two temperature-dependent “feedback” mechanisms for lowering shear resistance during slip have been proposed: friction-melting (McKenzie and Brune, 1972), and transient thermal pressurization of fault zone fluids (Sibson, 1973). Both of these mechanisms could lead to a high degree of stress relief during rupture and high seismic efficiency, provided fluids can be contained within the seismic slip zone. However, a variety of dynamic slip-weakening mechanisms that are not temperature-dependent are also under consideration (see Chapter 35 by Brune and Thatcher).

3.2.1 Friction Melting

Taking account of the evidence for slip localization, friction-melting requiring $\Delta T \rightarrow 1000^\circ\text{C}$ might be expected to be widespread in seismically active crustal fault zones (McKenzie and Brune, 1972). Fault-generated pseudotachylite friction-melts have been reported principally from fault zones developed in crystalline rocks, developed usually on individual faults with comparatively low total displacement (Sibson,

FIGURE 5 (a) Temperature increase in a shear zone of thickness, s , for $\tau_{fr} = 10$ and 100 MPa and various slip values, u , assuming uniform adiabatic heating with specific heat $c_p = 1000 \text{ J kg}^{-1} \text{ } ^\circ\text{C}$. (b) Geological constraints on the thickness of the seismic slip zone (PDZ, principal displacement zone).

1975; Magloughlin and Spray, 1992). They are most commonly associated with cataclasites but are sometimes hosted by mylonites where they appear to have been generated along transient brittle discontinuities within otherwise ductilely deforming shear zones (White, 1996; Takagi *et al.*, 2000). However, pseudotachylytes are comparatively rare in exhumed mature fault zones, raising an important issue as to whether their scarcity is apparent (resulting from cataclastic reworking and hydration), or whether seismic friction-melting in fault zones is a genuinely rare phenomenon inhibited by other mechanisms.

3.2.2 Thermal Pressurization of Fluids

Sudden power dissipation in fluid-saturated fault zones may boost ambient intergranular fluid-pressures by thermal pressurization (possibly aided by dehydration of clay-gouge), reducing kinetic shear resistance in accordance with Eq. (2) and inhibiting the larger temperature increases needed for melting (Sibson, 1973). Under constant volume conditions, $\Delta T \sim 100^\circ\text{C}$ is sufficient to raise initial hydrostatic to near-lithostatic fluid pressure levels. Additional boosting of fluid-pressure may result from dilatant crack closure accompanying shear stress release. Efficacy of all these mechanisms in reducing shear resistance depends critically on permeability adjacent to the slip surface (Lachenbruch, 1980; Mase and Smith, 1987) (see Section 5.2). However, thermal pressurization of fault zone fluids provides a physical explanation for the general scarcity of pseudotachylyte and its restriction to small displacement faults in dry crystalline rocks.

4. Structural Geometry of Crustal Fault Systems

The complex 3D finite structure of fault systems has been investigated by structural mapping, geophysical imaging, and oilfield drilling for over 150 years but only in the past three decades have higher resolution earthquake locations made it possible to correlate mainshock ruptures and aftershock activity with details of fault structural geometry. Earthquake ruptures are often viewed as increments of brittle fault growth because the incremental change in shear strain associated with an individual rupture of length, L_i , and average displacement, d_i , is typically:

$$10^{-4} > d_i/L_i > 10^{-5} \quad (6)$$

(Wells and Coppersmith, 1994). However, the ratio of finite displacement to total fault length on bounded faults generally lies in the range:

$$10^{-1} > d_f/L_f > 10^{-3} \quad (7)$$

(Schlische *et al.*, 1996), implying that faults, over longer time periods, are comparatively “ductile” structures with significant wallrock strains.

Moreover, the complexity of the finite deformation state is generally hard to explain solely in terms of the superposition of successive coseismic slip increments. Fault surfaces are frequently nonplanar; associated wallrock deformation may include large-strain fold structures with penetrative fabric development, as well as subsidiary faulting and fracturing distributed over broad regions. A substantial aseismic component of deformation has clearly contributed to this finite complexity.

4.1 “Anderson–Byerlee” Frictional Fault Mechanics

Anderson (1951) evolved a dynamic classification of faults by assuming: (i) that trajectories of the principal compressive stresses ($\sigma_1 > \sigma_2 > \sigma_3$) in the crust are constrained to be either vertical or horizontal because of the Earth’s free surface; and (ii) that faults form according to the Coulomb failure criterion as planar surfaces containing σ_2 and lying at an angle, $\theta_i = 0.5 \tan^{-1}(1/\mu_i)$, to σ_1 where μ_i is the coefficient of internal friction. For most rocks, $0.5 < \mu_i < 1.0$, so that $\theta_i = 27 \pm 5^\circ$ (Jaeger and Cook, 1979). Thrust faults ($\sigma_v = \sigma_3$) and normal faults ($\sigma_v = \sigma_1$) should therefore have initial dips of $27 \pm 5^\circ$ and $63 \pm 5^\circ$, respectively, while strike-slip (wrench) faults ($\sigma_v = \sigma_2$) should be vertical. Note that, strictly, Anderson’s classification relates only to the initiation of brittle faults in intact crust.

Some notion of the extent to which larger displacement faults exhibit “Andersonian” behavior may be gained from dip distributions obtained from moderate-to-large ruptures ($M > 5.5$) on reverse and normal faults that are close-to-pure dip slip (Fig. 6) to which two-dimensional (2D) reactivation analysis is applicable (Colletini and Sibson, 2001). Also shown is the ratio of differential stress to effective vertical stress required for reactivation of cohesionless reverse and normal faults at different orientations; note that optimal reactivation is more acutely defined for reverse faults. For the typical range of rock friction coefficients, $0.6 < \mu_s < 0.85$ (Byerlee, 1978), reshear occurs at the lowest stress ratio when a fault is oriented at the optimal reactivation angle, $30^\circ > \theta_r^* > 25^\circ$, to σ_1 , with frictional lock-up (for $\sigma_3' = (\sigma_3 - P_f) > 0$) occurring when $60^\circ > \theta_r = 2\theta_r^* > 50^\circ$ (Fig. 7).

On the assumption of horizontal and vertical stress trajectories, it is apparent that the dip ranges for both reverse and normal fault ruptures are consistent with $\mu_s \sim 0.6$, with lock-up occurring at $\sim 60^\circ$ and some evidence for optimal orientation of reverse faults at $\theta_r = 25\text{--}35^\circ$. Field and seismological observations confirm that strike-slip faults do tend to be subvertical, whereas the majority of reverse faults are thrusts with $\delta < 45^\circ$, and the majority of normal faults have $\delta > 45^\circ$ (as in the rupture dip ranges), all in generally accordance with “Anderson–Byerlee” expectations. Widespread oblique slip suggests, however, that many earthquakes are occurring on inherited faults reactivated in the present stress regime (Zoback, 1992).

Notable exceptions do, however, exist: for example, very low-angle normal faults that were apparently active to large displacements at very low dips ($\delta < 15^\circ$), often associated with metamorphic core complexes (Lister and Davis, 1989; Wernicke, 1995), and high-angle reverse faults ($\delta > 45^\circ$), some clearly developed by compressional reactivation of former normal faults during positive tectonic inversion (Hayward and Graham, 1989). Several

FIGURE 6 Dip distributions for reverse and normal dip-slip $M > 5.5$ ruptures with slip vector lying within $\pm 30^\circ$ of dip direction (data updated from Sibson and Xie (1998), Jackson and White (1989), and Colletini and Sibson (2001)). Dashed lines denote the expected angle of frictional lock-up for different friction coefficients, μ_s , on the assumption of vertical and horizontal stress trajectories. Reactivation parameter $(\sigma_1 - \sigma_3)/\sigma_v'$ (calculated for $\mu_s = 0.6$) provides a measure of the relative ease of reactivation of differently oriented faults.

large strike-slip systems, including the San Andreas fault, remain active though apparently oriented at very high angles to regional σ_1 trajectories (Mount and Suppe, 1992).

These structures raise important questions as to whether Byerlee frictional coefficients are universally applicable, or how often and under what conditions stress trajectories depart from the subhorizontal and subvertical within the seismogenic crust (Westaway, 1998). An important related issue is whether seismic increments of deformation that contribute to a complex finite deformation remain close to “Andersonian” or are themselves inherently more complex.

FIGURE 7 Sets of initially “Andersonian” normal and reverse faults undergoing “domino” rotation to frictional lock-up at $\theta \sim 55\text{--}60^\circ$ to σ_1 . Light dashed lines indicate orientations of secondary fault sets expected to develop after lock-up.

4.2 Fault Populations and Scaling Relationships

Crustal deformation is distributed on different-sized faults with larger faults accommodating greater finite displacements than small. Despite earlier suggestions of power-law relationships (Walsh and Watterson, 1988; Marrett and Allmendinger, 1991), a common linear scaling relationship between finite fault displacement, d_f , and fault length, L_f , appears to hold over eight orders of magnitude irrespective of faulting mode, though the bulk of the data comes from normal fault populations (Schlische *et al.*, 1996). On average, fault length increases linearly with displacement according to:

$$d_f \sim 0.01 L_f \quad (8)$$

a relationship consistent with post-yield fracture mechanics (Cowie and Scholz, 1992).

Size-frequency analysis generally reveals a power-law distribution for faults in continental crust, reflecting a self-similar fractal distribution over at least some scale ranges. An initial fault distribution nucleating on random heterogeneities

“self-organizes” by fault growth, interaction, and coalescence to a fractal pattern of clustered faulting where the bulk of the deformation is accommodated by the larger structures which “shield” adjacent areas from fault growth (Sornette *et al.*, 1990; Cowie, 1998). Note, however, that fault populations in deforming oceanic crust near midocean ridges tend to follow an exponential distribution, with a length scale perhaps imposed by the restricted width of the active rift zone or by the thinness of the brittle layer (Cowie, 1998).

4.3 Fault Segmentation and Linkage

Major fault zones at both brittle and ductile levels of the crust are commonly segmented with individual fault segments, either planar or curved, linked in 3D through a variety of subsidiary structures (Davison, 1994). Segmentation may arise from earlier growth and coalescence of previously independent faults; evidence exists that the degree of segmentation on strike-slip faults decreases with finite displacement, affecting seismic style and maximum rupture size (Wesnousky, 1988).

Linkage between adjacent fault segments may be “hard”, involving discrete linking faults or “soft,” involving distributed deformation (Walsh and Watterson, 1991). For example, en échelon normal faults may be linked by “hard” transfer faults sharing a common slip-vector, or by a “soft” relay ramp involving distributed warping between the segments (Fig. 8). An important distinction may also be made between conservative and nonconservative fault linkages depending on whether or not slip transfer involves local volume change (King, 1986). Transfer faults, sharing a common slip vector with adjacent thrust or normal fault segments, are an example of conservative linkage.

Nonconservative linkages include discontinuous jogs (or stepovers) developed perpendicular to slip vectors between en échelon fault segments (Fig. 8). Jogs may be classified as dilational ($\Delta\bar{\sigma} < 0$) or contractional ($\Delta\bar{\sigma} > 0$), depending on the change in mean stress within the jog accompanying slip transfer, and may develop on all types of fault with cross-fault dimensions ranging from millimeters to kilometers (Segall and Pollard, 1980).

4.4 Crustal Fault Systems

Strictly in a kinematic sense, the dominant modes of faulting at the three fundamental classes of plate boundary (convergent, divergent, and transform) correspond to Anderson’s three basic types of fault (thrust, normal, and strike-slip). In reality, however, each type of boundary is generally associated with a range of crustal faulting modes that are concurrently active. The particular aim here is to emphasize those aspects of the structural geometry of commonly encountered crustal fault systems that are relevant to the interpretation of shallow earthquakes.

FIGURE 8 Map views of common linkage structures in contractional (a), extensional (b), and strike-slip (c) fault systems. Transfer faults are conservative only when hard-linked and perfectly aligned with the regional transport direction. Non-conservative links such as dilational and contractional jogs may also occur along dip-slip faults. Also shown are possible rupture directivity effects associated with isolated fault bends.

4.4.1 Contractional Reverse Fault Systems

The seismotectonics of reverse fault systems have been reviewed by Yeats *et al.* (1997). In island and mountain arcs, interplate motion is primarily accommodated on the “mega-thrust” at the subduction interface with subsidiary thrusting in the fore-arc basin on the subduction hanging wall and on opposite-vergent thrusts in the back-arc. Thrust faulting likewise dominates the foreland and hinterland flanks of collision orogens. Local areas of thrusting may also develop in association with contractional irregularities on strike-slip faults. Steeper reverse faulting characterizes formerly rifted crust undergoing shortening.

3D complexity revealed within major fold-thrust belts, both across and along strike, by intensive oil–gas exploration has given rise to an equally involved structural terminology (Boyer and Elliott, 1982; McClay, 1992). Deformation may be largely restricted to the sedimentary cover sequence detached from the underlying crystalline basement (“thin-skinned” thrusting) or may actively involve the basement underlying the cover sequence (“thick-skinned” thrusting);

the latter commonly involves compressional reactivation of basement-penetrating normal faults inherited from previous crustal extension. Structural complexity arises principally from thrust development at low angles to anisotropy and subhorizontal competence layering within the rock-mass. Characteristic length scales are imposed within thrust assemblages by competent layers which range in thickness from individual beds to the elastic seismogenic lid of the crust.

These high-competence layers serve as σ_1 stress guides at various stages of the evolution of a thrust complex (Fig. 9), deflecting evolving thrusts into flat–ramp–flat assemblages and promoting buckling instabilities. Subsidiary deformation is mostly concentrated in the hanging walls of these “staircase trajectory” thrusts with the development of fault-bend and fault-propagation folds, backthrusts, wedging, and pop-up structures (Suppe, 1985; McClay, 1992). Along-strike complexity arises from transfer (tear) faults and lateral footwall ramps developed subparallel to the overall slip vector, and from oblique ramps.

FIGURE 9 Fault bend and fault propagation folds associated with a “staircase” thrust system in layered crust (after McClay, 1992). Thrust ramps form in competent layers which serve as stress guides deflecting principal stress trajectories.

Cross-strike complexity of thrust systems does much to explain the observed dip-distribution of reverse fault ruptures (Fig. 6). The spread of defined reverse rupture dips above optimal orientation ($\delta \sim 30^\circ$) and the notable subsidiary peak at $\delta = 50 \pm 5^\circ$ can be accounted for by progressive “domino” steepening of stacked imbricate thrusts (Fig. 7) with an additional contribution from inherited normal faults reactivated in compression (Sibson and Xie, 1998). Paucity of positively discriminated thrust ruptures with very low dips ($\delta < 15^\circ$) [though widespread in the frontal Himalayas (Molnar and Lyon-Caen, 1989; Powers *et al.*, 1998)] suggests that it is generally the ramps in flat-ramp-flat assemblages that fail in moderate-to-large earthquakes.

4.4.2 Extensional Normal Fault Systems

Reviews of the seismotectonics of extensional fault systems are provided by Yeats *et al.* (1997), Roberts and Yielding (1994), and Jackson and White (1989). At midocean ridges and in some continental rifts, parallel sets of predominantly inward-facing normal faults tend to be symmetrically disposed about the rift axis. In other regions of distributed continental extension such as the Basin and Range province of western North America, sets of normal faults with consistent facing direction may be associated with series of tilted half-grabens (Fig. 7). In island arc systems, arc-parallel normal faulting may develop in association with magmatic activity in back-arc basins and, in the vicinity of the outer rise, through bending of the subducting slab. Normal faulting may also develop orthogonal to thrusting in collision orogens to allow lateral distension of the uplifted welt.

Although there is considerable evidence from reflection profiling and drilling for the existence of listric normal faults at comparatively shallow depths (< 5 km) in sedimentary basins, major seismically active normal faults appear approximately planar in cross-strike profile. However, they are corrugated at various scales along strike, often presenting

a somewhat scalloped appearance (Stewart and Hancock, 1991). Extensional stress fields with σ_3 horizontal promote the development of parallel-striking vertical extension fractures. In magmatically active terrain, normal faults are associated with parallel-striking dikes and fissures (Gudmundsson, 1995). Elsewhere, especially in the near-surface, associated fractures may be infilled with hydrothermal veins forming a fault-fracture mesh (Sibson, 1996) (Fig. 3).

In continental regions, individual segments of normal faults typically extend for 10–30 km along strike, distances that are 1–2 times the usual thickness of the seismogenic crust in areas of rifting (Machette *et al.*, 1991), but longer segments are known, for instance in the East African Rift system where the seismogenic zone is notably deeper (Jackson and Blenkinsop, 1997). “Large” normal fault ruptures occupying the full depth of the seismogenic zone generally involve one or more segment lengths within these systems. Individual normal fault segments may be linked to parallel-facing and opposite-facing segments through a variety of linkage structures which include “soft” relay ramps and diffuse accommodation zones, and “hard” linkage in the form of clear-cut transfer faults (Morley *et al.*, 1990; Walsh and Watterson, 1991; McClay and Khalil, 1998).

Progressive crustal extension may be accommodated by the “dominoing” of upper crustal blocks separated by parallel-facing normal faults that extend through the seismogenic layer (Fig. 7). Block rotation may continue until fault dips approach lock-up at $\delta \sim 30^\circ$ and helps to account for the observed distribution of active normal fault dips (Fig. 6). Very low-angle normal faults (detachments) have been usually described in association with metamorphic core complexes (Wernicke, 1995), but more recently in the midocean ridge environment (Blackman *et al.*, 1998). The circumstances under which such structures form and remain active, and their seismogenic role, remain unclear.

4.4.3 Strike-Slip Fault Systems

Comprehensive reviews of strike-slip fault geometry, principally in continental and island arc environments, are provided by Yeats *et al.* (1997), Woodcock and Schubert (1994), and Sylvester (1988). Geomorphic characteristics of oceanic transforms are summarized by Fox and Gallo (1986). Continental strike-slip faulting occurs in a range of tectonic environments and patterns: (1) as often braided systems of subparallel strike-slip faults defining continental transforms; (2) as trench-parallel strike-slip faults contributing to strain partitioning along island and mountain arcs; (3) as indent-related strike-slip faults in collisional orogens; (4) as local transfer structures in predominantly dip-slip fault systems; and (5) as distributed strike-slip faults, developed in either parallel or conjugate sets, accommodating crustal deformation over broad areas, often with significant rotations of crustal blocks about vertical axes (e.g., Luyendyk, 1991).

Seismological studies confirm that the vast bulk of pure strike-slip motion is accommodated on subvertical tabular fault zones. Geological mapping has revealed patterns of ductile strike-slip shear zones ranging up to tens of kilometers in thickness in exhumed middle and lower continental crust, suggesting that in at least some circumstances major strike-slip faults continue downward through the lower crust as localized aseismic shear zones which maintain the anastomosing complexity observed in the upper brittle crust (e.g., Hanmer, 1988; Corsini *et al.*, 1996). Patterns of finite strain associated with strike-slip faults tend to be further complicated by components of transpression and/or transtension which may develop at various stages of the fault's history (Dewey *et al.*, 1998).

In map view, major strike-slip faults are irregular and segmented on a range of scales with isolated fault bends and en échelon stepovers which may be continuous (releasing and restraining bends) or discontinuous (dilational and contractional jogs). Unlike the systematic stepping of Riedel shear arrays which characterize strike-slip rupture traces on cross-strike scales of 1–10 m or so (Tchalenko, 1970), no consistent sense of stepping is usually apparent for these major irregularities which have cross-strike scales of 1–10 km. Such major structural irregularities which, from aftershock studies appear to extend through much of the seismogenic zone (Reasenber and Ellsworth, 1982), may perturb or arrest rupture propagation and contribute to characteristic earthquake behavior (Harris and Day, 1993; Sibson, 1985). Wesnousky (1988) showed that the frequency of major structural irregularities on strike-slip faults decreases with finite displacement.

Major irregularities induce subsidiary deformation. Thrusting develops in the vicinity of restraining bends and within contractional jogs, and normal faulting occurs near releasing bends and within dilational jogs. Such irregularities serve as local amplifiers of vertical motion within the strike-slip system but many appear to be comparatively short-lived (Brown *et al.*, 1991).

5. Fluid Activity in Fault Zones

The role of aqueous fluids in weakening fault zones and in earthquake rupture processes is contentious but potentially of enormous importance (Hickman *et al.*, 1995). Allowing for cementation or some inherent cohesive strength, C , within the fault zone, frictional fault strength may generally be represented by:

$$\tau_{fr} = C + \mu_s \sigma_n' = C + \mu_s(\sigma_n - P_f) \quad (9)$$

so that fluid overpressures may induce physical weakening by reduction of effective normal stress (Hubbert and Rubey, 1959), as demonstrated by the triggering of seismic activity through deep fluid injection (Nicholson and Wesson, 1990; and Chapter 40 by McGarr *et al.*).

Fault instability may therefore be induced, not just by rising shear stress, τ , as is often assumed, but by increased fluid pressure or decreased normal stress, or by some combination of all three factors. Chemical weakening of faults by aqueous fluids may also occur through processes such as stress corrosion cracking, diffusive mass transfer, reaction softening, and enhanced crystal plasticity in the ductile regime through hydrolytic weakening of silicates (Hickman *et al.*, 1995; and Chapter 32 by Lockner and Beeler).

5.1 Fluid Manifestations

Direct evidence of fluid involvement with earthquakes comes from observations of substantial postseismic discharge in the vicinity of active faults (Muir-Wood and King, 1993), the greatest effects occurring in the vicinity of normal fault ruptures. Other manifestations of fluid/gas migration in and around active fault zones are reviewed by King and Igarishi in Chapter 39. Early suggestions of a link between global CO₂ discharge and seismic belts (Irwin and Barnes, 1980) have been borne out by recent geochemical studies that support the existence of a large CO₂ flux through the San Andreas fault system (averaging >1 tonne per meter strike-length per year) (Kennedy *et al.*, 1997).

Studies of exhumed fault zones provide abundant evidence for their role as fluid conduits at all crustal levels. Hydrothermal alteration assemblages and syntectonic vein systems provide information on fluid compositions at high structural levels (Parry, 1998), whereas metasomatic effects suggest that integrated fluxes of 10^3 – 10^5 m³ m⁻² and water/rock ratios <10³ are common in ductile shear zones developed in the middle to deep crust (McCaig, 1997). Compositions of fault fluids are highly variable (Parry, 1998); inferred sources include meteoric waters, diagenesis and metamorphism at depth, local magmatism, and perhaps mantle-derived fluids rich in CO₂.

5.1.1 Fault-hosted Mineralization

Hydrothermal mineral deposits result from focused flow of large fluid volumes and are commonly hosted in and around ancient fault zones. Solubility criteria, incremental vein textures, and the need for rapid transport between different P – T environments to promote instability and localized precipitation suggest that mineralization results from multiple episodes of rapid flow. Although formation of major fault-hosted deposits clearly involves special circumstances, they provide important evidence for fluid redistribution tied to episodes of incremental fault slip and permeability renewal. Two principal habitats are recognized: the shallow *epizonal* environment usually associated with extensional–transtensional faulting near the top of the seismogenic zone, and the *mesozonal* environment developed toward the base of the seismogenic zone in compressional–transpressional regimes.

Abrupt reductions in fluid pressure induced by seismic slip increments appear integral to hydrothermal precipitation in both environments, though the mechanisms differ in detail (see below and Fig. 11).

5.1.1.1 Epizonal Mineralization

Most epizonal deposits (e.g., Au-Ag and Pb-Zn-Ag) occupy high-permeability meshes of steep extension fractures and subsidiary minor faults developed at shallow (<1–2 km) depths in dilational irregularities associated with normal and strike-slip fault systems, which localize ascending hydrothermal plumes and also allow mixing of fluids from different sources (Henley, 1985; Sillitoe, 1993). An association with felsic magmatism is usually apparent for the Au-Ag deposits. Dilational structures typically comprise a mesh of extension veins and subsidiary shears with wallrock breccias derived from multiple episodes of brecciation and hydrothermal cementation.

5.1.1.2 Mesozonal Mineralization

Mesozonal Au-quartz veins, by contrast, are mostly hosted in the subgreenschist to greenschist grade semiductile root zones (10 ± 5 km depth) of fault systems developed in compressional–transpressional tectonic regimes without clear-cut magmatic associations. The vein systems may extend over 1–2 km vertically, often comprising fault-veins developed on steep reverse or reverse-oblique faults intermeshed in mutual crosscutting relations with arrays of flat-lying extension veins (Sibson *et al.*, 1988; Cox, 1995). These incrementally developed vein systems, inferred to develop through extreme fault-valve action (see below), hold special significance for the shallow earthquake source. They demonstrate that, in at least some instances, near-lithostatic fluid-pressures are localized within fault zones developed in crystalline rock assemblages around the base of the seismogenic zone, with large-amplitude fluid-pressure cycling coupled to the seismic stress cycle (see Fig. 11) (Robert *et al.*, 1995; Parry, 1998).

5.2 Structural Permeability in Fault Zones

Fault permeability is highly variable, depending strongly on the host rock assemblage as well as the level of fault activity. Inactive faults in sedimentary basins variously serve as sealing barriers to fluid migration or as cross-stratal conduits for fluid flow (Jones *et al.*, 1998). Brittle faults developed in initially high-porosity sedimentary rock, through comminution and porosity collapse, tend to be relatively impermeable in comparison with the wallrock (Antonellini and Aydin, 1994), whereas faults formed in initially low-porosity rocks enhance permeability through cataclastic brecciation and subsidiary fracturing. Studies of exhumed fault zones in crystalline rock suggest that a low-permeability core of extremely fine-grained ultracataclasite is often flanked by a comparatively high-permeability “damage zone” of distributed fracturing (Evans *et al.*, 1997).

Evidence from geothermal fields, fault mineralization, and experimental work suggests, however, that fault permeability in active hydrothermal environments can be self-destructive over time periods that are short compared with earthquake recurrence intervals (Morrow *et al.*, 2001; Hickman *et al.*, 1995). Only those fractures that are favourably oriented for shear reactivation remain hydraulically conductive (Barton *et al.*, 1995). Permeability within seismically active fault zones is therefore dynamic, with faulting, fracturing, microcracking and brecciation competing with processes of permeability destruction which include hydrothermal alteration accompanying gouge formation, microcrack healing, hydrothermal cementation of fractures, and solution-precipitation (Parry, 1998). Fault permeability is likely to be highest immediately postrupture (Brown and Bruhn, 1996), progressively diminishing through the interseismic period.

5.3 Fluid Overpressures

Hydrostatic fluid pressures prevail in fluid-saturated rocks where interconnected pore space and fracture systems are freely linked through to the Earth’s surface as has been widely demonstrated for crystalline intraplate cratonic crust (Townend and Zoback, 2000). However, fluid pressures in deforming crust are commonly elevated well above hydrostatic at depths of more than a few kilometers (Fyfe *et al.*, 1978). Some earthquakes clearly nucleate in overpressured crust, for example, in fore-arc regions of active thrust faulting (e.g., the 1999 *M* 7.6 Chi-Chi, Taiwan earthquake), but there is debate on the extent to which major fault zones are routinely overpressured above hydrostatic and whether such overpressuring is restricted to the immediate vicinity of the fault zones (Fig. 10).

Lowered frictional strength from overpressuring [Eq. (2)] could contribute to the apparent weakness of the San Andreas fault system (e.g., Streit, 1997), but there are important questions as to how such overpressures are maintained and the extent of the net fluid flux through the fault zone. Rice (1992) suggested a model where overpressuring is sustained by a continuous upwards fluid flux through the fault zone (large net flux), whereas Byerlee (1993) supposes fault zones to be subdivided into overpressured compartments separated by seals, in each of which the pressure gradient remains hydrostatic, with local fluid redistribution occurring at the time of earthquakes. Sleep and Blanpied (1994) put forward a model in which fluid overpressure is “regenerated” in each seismic cycle through compaction of fault gouge (low net flux).

Evidence for fluid overpressures and large-amplitude cycling of fluid pressure in some exhumed fault zones has been derived from associated syntectonic vein systems developed in both sedimentary and crystalline host rocks and their contained fluid inclusions (Robert *et al.*, 1995; Parry, 1998). Moreover, intense veining in strongly mineralized fault zones suggests focused flow of very large fluid volumes (e.g., Cox, 1995).

FIGURE 10 Hypothetical fluid-pressure profiles and associated frictional shear resistance (normalized to hydrostatic τ_{fr}) through the FR regime of an active fault zone. Dashed lines (a, b) represent two of a range of smooth progressions from hydrostatic to near-lithostatic fluid pressures towards the base of the seismogenic zone; (c) represents a profile through a compartmentalized fault zone with hydrostatic gradients between each sealing horizon (stippled).

5.3.1 Coseismic Pressure Changes

As previously discussed (Section 3.2.2), frictional dissipation during seismic slip may boost intergranular fluid-pressures significantly by thermal pressurization, thus reducing kinetic shear resistance. Fluid pressure may also be locally reduced by rapid slip transfer across dilational jogs, the transient imbalance in fluid-pressures sometimes inducing hydraulic implosion of wallrock into the dilatant site (Sibson, 1985).

5.4 Mechanisms for Fluid Redistribution

Several dynamic mechanisms have been invoked to account for fluid redistribution linked to the earthquake stress cycle but their relative importance at different crustal levels and in different tectonic regimes is uncertain. More than one mechanism may operate at any time and place.

5.4.1 Dilatancy Pumping

Early suggestions of cyclical, regional-scale microcrack dilatancy operating at high (kilobar) levels of differential stress in the crust adjacent to active fault zones and capable of large-scale fluid redistribution (Scholz *et al.*, 1973) have not been substantiated, though the search for other forms of stress-dependent dilatancy continues (Crampin, 1994). Various other forms of cyclical dilatancy have been proposed, some restricted to the fault zones themselves (Sibson, 1994; and Chapter 32 by Lockner and Beeler). However, until the stress levels driving faulting and appropriate constitutive dilatancy laws are resolved, it is not possible to evaluate their relative contributions to fluid redistribution in the crust.

5.4.2 Mean Stress Cycling

Tectonic shear stress on faults cannot in general be changed without also changing fault-normal stress (altering its frictional strength) and the level of mean stress ($\bar{\sigma} = [\sigma_1 + \sigma_2 + \sigma_3]/3$) (Sibson, 1991). For dip-slip faults, coupled changes in mean stress ($\Delta\bar{\sigma}$) are of the same order as the shear stress drop ($\Delta\tau$), but the coupling is diametrically opposite for reverse and normal faults. Reverse faults are *load-strengthening* with mean stress increasing during loading only to decrease at failure, whereas normal faults are *load-weakening* with mean stress increased postfailure. Closure of subvertical cracks in the near-surface from increased horizontal stress postfailure may account for the large surface effusions sometimes observed following rupture of normal faults (Muir-Wood and King, 1993).

5.4.3 Redistribution around Rupture Irregularities

Rupturing leads to abrupt postfailure changes in mean stress localized around structural irregularities (Segall and Pollard, 1980), with fluids redistributed from areas of raised to areas of lowered mean stress (Nur and Booker, 1972). Aftershock activity associated with fluid influx tends to concentrate in regions of reduced mean stress at fault tips and in dilational jogs and bends which also serve to localize geothermal systems in extensional–transtensional fault systems, forming important sites for mineralization. Dilational bends and jogs (Fig. 8) act essentially as “suction pumps.” Rapid slip transfer during rupture propagation leads to abrupt localized reductions in fluid pressure below ambient (hydrostatic?) levels (Fig. 11), triggering brecciation by hydraulic implosion accompanied by episodes of boiling and mineral precipitation at shallow depths in geothermal systems (Sibson, 1985). Induced suctions contribute to rupture perturbation or arrest, promoting time-dependent slip transfer across the jog through the aftershock phase as fluid pressures restore to background levels (Peltzer *et al.*, 1996).

5.4.4 Fault-Valve Action

Valving action occurs wherever ruptures breach impermeable barriers bounding overpressured zones which may be restricted to the fault zones themselves or extend into the surrounding crust. Postseismic fluid discharge upwards along the transient permeability of the rupture zone causes local reversion toward a hydrostatic fluid pressure gradient before hydrothermal self-sealing occurs, and fluid overpressure rebuilds at depth (Fig. 12). Timing of successive failure episodes is then controlled by the cycling of tectonic shear stress, fluid pressure, and frictional fault strength through the interseismic period (Sibson, 1992).

The association of mesozonal gold–quartz vein systems with steep reverse faults that, demonstrably, were severely mis-oriented for frictional reactivation at the time of mineralization

FIGURE 11 Fluid-pressure cycling in relation to earthquake (EQ) rupturing. (a) Schematic relating fault permeability, k , to the earthquake shear stress cycle; (b) "suction-pump" effect at dilational fault jog; (c) fault-valve action in overpressured crust (P_h and P_l are hydrostatic and lithostatic fluid-pressure levels, respectively).

has led to the interpretation that such systems developed through extreme fault-valve action (Sibson *et al.*, 1988; Robert *et al.*, 1995). The compressional stress field served to contain deep-sourced, lithostatically overpressured H_2O-CO_2 fluids until fault rupture, followed by focused discharge along the faults. Valving action may also promote oil and gas migration in overpressured sedimentary basins. Widespread development of syntectonic fault veins, coupled with the growing evidence for fluid-pressure cycling in crustal fault zones (e.g., Parry, 1998), suggest that minor valving action involving small fluid volumes is widespread, leading to significant strength variations that affect rupture nucleation and recurrence.

6. Discussion

The study of exhumed fault zones for the information they can yield on earthquake source processes, both from their structural geometry and from fault-rock assemblages, is in its infancy. Preliminary fault zone models established from such investigations, coupled with the results of experimental rock deformation studies, have already provided insights into factors governing the depth and style of seismic activity in deforming crust. One limitation of most existing models is their monolithologic character (largely based on the deformation of granitoid material at different crust levels); future poly-lithologic fault zone models should take greater account of compositional heterogeneity over a range of scales. Continued

FIGURE 12 (a) Fault failure governed by the coupled cycling of shear stress and fluid pressure through fault-valve action in overpressured crust. (b) Time-dependent fluctuations in shear stress, τ , and frictional strength, τ_{fr} , accompanying successive earthquake ruptures (EQ) in the fault-valve cycle (after Sibson, 1992).

efforts are needed to reconcile shear strength profiles inferred from fault zone models with the apparent weakness of major transcrustal fault zones. However, there are indications that the answer lies in the chemical and physical weakening effects of hydrothermal fluids, both from overpressuring which may be localized within the fault zone itself, and through reaction weakening leading to the development of phyllosilicate-rich material.

Despite problems arising from structural overprinting, developments in microstructural and microthermometric fluid-inclusion techniques will help to discriminate deformation and fluid processes occurring at different stages of the earthquake stress cycle, and should also lead to better geobarometric constraints on fault-rock assemblages. Isolating the deformation characterizing an individual rupture at different crustal levels will vastly improve understanding of dynamic slip processes and the shear stress levels driving faulting.

New seismological techniques, especially high-resolution location of microearthquakes delineating details of fault zone internal structure, coupled with investigatory drilling to sample active fault zone material and make direct measurements of physical conditions around the earthquake source, will help to test and elaborate more advanced fault zone models.

Acknowledgments

I would like to thank Dave Hill, Tom Hanks, Bill Ellsworth, Art McGarr, Steve Hickman, and many others at Menlo Park for their efforts in my seismological education over the past 20 years. Bob Yeats and Toshi Shimamoto provided helpful reviews of the manuscript.

1. Introduction

Paleoseismology is the study of earthquakes decades, centuries or millennia after their occurrence (Yeats and Prentice, 1996). Paleoseismic studies typically focus on prehistoric or pre-instrumental earthquakes (Sieh 1981; Wallace, 1981; McCalpin and Nelson, 1996) to supplement the historic record of seismicity. The time between surface ruptures of active faults is on the order of decades for the fastest-moving faults to thousands or tens of thousands of years for more numerous but less-active faults (see Table 1 in Chapter 29 by Sibson). Modern scientific observation and analysis of earthquakes have occurred for a small fraction of this time, so there are few observations on the spatial and temporal characteristics of fault ruptures over multiple seismic cycles (Sieh, 1996). Paleoseismic investigations provide data on earthquake occurrence and the seismogenic behavior of individual faults that complement modern observations of earthquakes, with important implications for scientific models and practical applications for seismic hazard assessment (Reiter, 1995).

Moderate to large earthquakes may generate surface rupture or induce permanent changes in the landscape and local environment. Under suitable conditions, evidence of earthquakes is preserved in the geologic record. Paleoeearthquakes are recognized by detailed observations and analyses of geologic or environmental conditions within fault zones or in tectonically or seismically active regions. Paleoseismic investigations yield information about the recency of fault movement, dates of previous earthquakes, recurrence times, average slip rate, and earthquake effects over time intervals ranging from decades to thousands of years. Paleoseismic data are applied toward estimating the magnitudes of past earthquakes, forecasting the magnitudes of future earthquakes (WGCEP, 1988; Reiter 1991), and identifying areas susceptible to fault rupture.

Paleoseismology is a subspecialty of seismology in that it focuses on earthquakes. However, the primary methods of paleoseismic data collection and analysis are drawn from geology and are distinctly different from analyses of seismic

waves conducted by geophysicists. Therefore, paleoseismology is sometimes considered to be a subspecialty of active tectonics or earthquake geology. Paleoseismology began to emerge as a distinct discipline in the late 1960s to mid-1980s. Summaries, compendia or review articles focusing on paleoseismology have been generated by Wallace (1981, 1986), Sieh (1981), Crone and Omdahl (1987), Vittori *et al.* (1991), Pantosti and Yeats (1993), Prentice *et al.* (1994), Serva and Slemmons (1995), Yeats and Prentice (1996), and Pavlides *et al.* (1999). Yeats *et al.* (1997) provide a comprehensive text on the geology of earthquakes with global coverage of active tectonics and paleoseismic studies. For a comprehensive text and reference on paleoseismology, the reader is referred to McCalpin (1996).

The purpose of this chapter is to summarize methods, contributions, and issues in paleoseismology. Topics include paleoseismic investigation methods, models, and applications. Issues in research and application are discussed in each section. Examples and references are chosen to highlight major concepts and findings rather than attempting to provide a comprehensive or geographically inclusive summary. Most examples are from western North America, and heavy emphasis is placed on studies of the San Andreas fault system. Discussions of faulting and seismic hazard assessment are treated more fully by Sibson (Chapter 29) and Somerville and Moriawaki (Chapter 65).

2. Investigation Goals and Methods

With few exceptions, earthquakes are generated by the movement of faults (Bolt, 1999). Therefore, paleoseismic research is directly or indirectly a study of faults and their surface expression. Paleoseismic investigation methods employ techniques from several geologic subdisciplines, including stratigraphic analysis, Quaternary geology, soil science, geomorphology, engineering geology, geochronology, and structural geology. Major objectives of paleoseismic studies include identification of recently active or seismogenic faults,

measurement of displacement (coseismic and long-term average), and establishing catalogs of paleoearthquakes. This section is organized by common goals of paleoseismic studies, rather than by disciplinary techniques, because most investigations employ a variety of techniques.

2.1 Fault Identification

Because earthquakes are generated by faults, the first step in any paleoseismic investigation is identification of a fault for study. An active fault is a fault that may have displacement within a future period of concern to humans (Wallace, 1981). Identification of active faults requires recognizing previous displacement and constraining the age of displacement. Therefore, an active fault is usually identified by associating it with tectonically deformed Quaternary-age materials or surfaces (e.g., Ziony and Yerkes, 1985).

2.1.1 Recognition of Tectonic Deformation

Paleoseismic investigation methods are only applicable to faults that cause recognizable tectonic deformation or environmental changes (e.g., submergence, erosion, anomalous deposition, or mortality) at or near the Earth's surface. Faults may be classified by average slip rate (see Table 1 in Chapter 29 by Sibson), type of displacement (strike slip, dip slip normal, dip slip reverse, thrust, or oblique slip), and depth (surface or blind). The depth, rate, and type of fault slip determine the amount and nature of fault-induced deformation at the surface. The faster the slip rate, the more active the fault and the more likely the fault can be recognized and characterized by paleoseismologists (Slemmons and dePolo, 1986). Faults that reach the surface are easier to recognize than blind faults, but they may rupture to the surface infrequently if they have low slip rates (see Chapter 29 by Sibson).

Paleoseismic data provide an incomplete record of earthquakes and fault rupture. Tectonic deformation due to fault slip may be difficult to recognize if rupture does not reach the surface, especially in intraplate regions (e.g., Lettis *et al.*, 1997). Earthquakes on blind faults may induce subtle surface deformations over broad areas (Stein and Yeats, 1989) or distributed evidence of shaking in disrupted sediments (Reiter, 1995). The existence of an active blind fault can be detected by geomorphic analysis (e.g., Bullard and Lettis, 1993; Keller and Pinter, 1996), by mapping Quaternary sediments and identifying areas of uplift (e.g., Grant *et al.*, 1999) or by recognizing effects of shaking that are not associated with known surficial faults (Reiter, 1995).

Effects of tectonic deformation can be enhanced or obscured by anthropogenic or natural processes such as weathering and erosion. If tectonic changes cannot be readily distinguished from changes induced by other mechanisms, then the results of paleoseismic studies may be biased toward higher or lower estimates of tectonic displacement. Such problems have been noted in a variety of tectonic and human environments (e.g., Ricci Lucchi, 1995; Obermeier, 1996; Nur, 2000).

2.1.2 Application of Geochronology

Geochronology is dating of earth materials, surfaces, and processes. Geochronology is essential for paleoseismology because it constrains dates of paleoearthquakes and average rates of fault displacement. The most useful geochronologic methods for paleoseismic investigations yield high-resolution ages for common, late Quaternary materials such as soils or buried flora and fauna (Lettis and Kelson, 2000). Table 1 summarizes geochronologic methods for dating Quaternary materials in fault zones. A detailed discussion of this complex topic is beyond the scope of this chapter. A comprehensive

TABLE 1 Classification of Quaternary Geochronologic Methods (Adapted from Noller *et al.*, 2000a)

Sidereal	Isotopic	Radiogenic	Chemical and Biologic	Geomorphic	Correlation
Dendrochronology	Radiocarbon	Fission track	Amino acid racemization	Soil-profile development	Stratigraphy
	Uranium series	Thermoluminescence	Rock-varnish cation ratio	Rock-varnish development	Paleomagnetism
Varve chronology	²¹⁰ Pb	Optically stimulated luminescence	Obsidian and tephra hydration	Scarp morphology and landform modification	Tephrochronology
	U-Pb, Th-Pb				Paleontology
Historical records		Electron-spin resonance	Soil chemistry	Rate of deformation	Tectites and microtectites
	K-Ar and ³⁹ Ar- ⁴⁰ Ar		¹⁰ Be accumulation in soils	Rate of deposition	Climate correlation
Sclerochronology and growth rings	Cosmogenic isotopes	Infrared stimulated luminescence	Lichenometry	Rock and mineral weathering	Astronomical correlation
				Geomorphic position	Stable isotopes
					Archeology

compilation and summary of Quaternary geochronologic methods and applications is provided by Noller *et al.* (2000b). The most commonly used methods are also described by McCalpin (1996) and Yeats *et al.* (1997).

Radiocarbon dating is the most widely used method for dating Holocene and latest Pleistocene earthquakes. The half-life of radioactive ^{14}C (5730 y) limits the application of radiocarbon dating to organic matter formed from carbon fixed within the last 50 000–60 000 y (Trumbore, 2000). The amount of ^{14}C in atmospheric CO_2 has varied in the past, particularly in the last few centuries due to anthropogenic emissions. To compensate for this variation, radiocarbon ages are calibrated to correspond to calendar ages (absolute ages). Calibrations based on tree rings and glacial varves extend back to the early Holocene. Calibration curves are not linear. Plateaus in the calibration curves limit the precision of radiocarbon dating (Trumbore, 2000). This problem is acute for the last few centuries. For example, Yeats and Prentice (1996) note that the two largest historic ruptures of the San Andreas fault in California, which occurred in 1857 and 1906, are indistinguishable using radiocarbon dating.

All methods listed in Table 1 have limitations and uncertainties. Uncertainty in geochronologic methods is a major source of uncertainty in paleoseismic data (Lettis and Kelson, 2000). In addition to uncertainty in calibration and accuracy of analysis, errors may be introduced in the selection, collection, and interpretation of field samples. Therefore, most paleoseismic studies employ multiple methods of dating to reduce uncertainty and allow cross-checking of results. Methods such as radiocarbon dating that yield accurate, high-precision ages of common or widely distributed materials are preferred. Recent improvements in geochronology methods and in the statistical treatment of dates have reduced uncertainties in previously published ages (e.g., Sieh *et al.*, 1989; Biasi and Weldon, 1994).

2.2 Chronologies of Earthquakes

Large earthquakes create features that may be preserved in the stratigraphic record and recognized by geological, geomorphic, environmental, or archeological analysis. Major effects of earthquakes include surface rupture, ground deformation, and ground failures due to shaking. Chronologies of earthquakes are developed by identifying and dating evidence of multiple paleoearthquakes along a specific fault, or by documenting evidence of shaking or tectonic deformation in a seismically active region. The longest chronology of paleoearthquakes spans 50 000 y, with a mean recurrence time of ~ 1600 y (Marco *et al.*, 1996).

For most Quaternary faults, the dates of prehistoric earthquakes are not known. Well-studied faults such as the San Andreas fault in California, and the North Anatolian fault in Turkey, have chronologies of only a dozen or so paleoearthquakes. Nonseismic processes can create features that appear

very similar to those generated by earthquakes (Ricci Lucchi, 1995; Obermeier 1996). The most commonly reported and least ambiguous paleoseismic data are derived from observations of surface ruptures.

2.2.1 Surface Rupture Investigations

Evidence of surface rupture can be observed directly in natural exposures or, more commonly, in trench excavations (see Figs. 1A and 1B on the Handbook CD-ROM, under the directory \30Grant). Paleoseismologists look for trench sites with distinct evidence of multiple ruptures and abundant material for dating. Trenches are generally excavated with a backhoe or similar excavation equipment. Shallow trenches in unconsolidated sediments may be dug by hand. Deep trenches must be stabilized with shoring, benching or sloping. Stabilization methods are chosen to maximize wall exposure. The maximum practical depth for typical trench investigations is 5 m.

Trench exposures are cleaned by scraping and brushing to highlight stratigraphy and faults. Geologists map the exposures with the aid of a string grid or survey control. The maps are called trench logs. Trench logs are supplemented with descriptive notes of observations and objective records such as photographs. Samples of datable material are collected after their locations have been documented on the trench log. A good trench log documents observations of stratigraphy and structure as objectively as possible. However, it is impossible to make an entirely objective log because construction of a log is partly an act of interpretation.

2.2.1.1 Recognition and Dating of Ruptures

The goal of logging is to recognize and record the number of surface ruptures and their stratigraphic position relative to datable material so that each paleoearthquake can be analyzed and dated as accurately as possible. Evidence of surface rupture is commonly called a paleoseismic event. The stratigraphic unit that was the ground surface at the time of the earthquake is referred to as the event horizon. Figure 1 shows typical stratigraphic and structural relationships that are used for recognizing and dating previous earthquakes (Lettis and Kelson, 2000). Figure 2 shows an example of a trench log from the San Andreas fault, with several paleoseismic events and event horizons marked with letters. The most useful criteria for identifying ruptures include multiple fault terminations at a single stratigraphic horizon, tilted and folded strata overlain by less-deformed strata, and colluvial wedges draped over fault scarps (Yeats and Prentice, 1996). Fault strands may die out and terminate below the surface, or be poorly expressed at the event horizon (Bonilla and Lienkaemper, 1990). Therefore, multiple exposures of a fault should be examined whenever possible to identify the event horizon with maximum confidence.

In some areas a fault cannot be examined with excavations because of a high water table, the presence of human

FIGURE 1 Diagrams illustrating stratigraphic and structural criteria used to identify the occurrence and timing of paleoearthquakes. Stratigraphy, faults, and soils are shown schematically. Dated samples at locations marked "A" predate the earthquake. Dated samples at locations "B" postdate the earthquake. Dated samples at "C" are not helpful for deciphering the chronology of past earthquakes because the sample may predate or postdate the earthquake. Where evidence of multiple earthquakes is present, locations A1 predate the earlier event and locations A2 postdate the earlier event and predate the later event. (From Lettis and Kelson, 2000.)

structures, or burial by younger sediments. Subsurface investigation methods such as cone penetrometer testing (CPT) and large diameter borings may be applied for these conditions (Grant *et al.*, 1997; Dolan *et al.*, 2000). These methods must be used in combination with other subsurface investigation methods such as seismic imaging, ground penetrating radar, and standard borings. There are greater

FIGURE 2 Example of a portion of a trench log from the San Andreas fault at Bidart Ranch in the Carrizo Plain, California. Letters indicate the approximate location of evidence for several paleoearthquakes (A, B, D, E?, F). Query indicates uncertainty. (From Grant and Sieh, 1994.)

uncertainties in the identification and dating of paleoearthquakes from subsurface investigations than from surface exposures.

The chronology of surface ruptures revealed by paleoseismic methods is a subset of the actual earthquake history. The paleoseismic record is spatially and temporally incomplete because the conditions required for preservation of earthquakes are not present at all times on all active faults. The minimum earthquake magnitude associated with surface rupture is about M_L 5 (Bonilla, 1988), so $M_L < 5$ earthquakes are rarely recognized in trench exposures. Surface faulting is commonly associated with $M > 6$ earthquakes (Wells and Coppersmith, 1994). Therefore, most paleoseismic events recognized in trenches represent $M \geq 6$ earthquakes. Nor have all faults been studied by paleoseismologists. Early paleoseismic studies focused on examining evidence of larger earthquakes ($M > 7$) because the data were relatively easy to interpret. Therefore, the published paleoseismic record of earthquakes contains less data on the occurrence of smaller ($M < 7$) earthquakes (McCalpin, 1996).

2.2.2 Regional Coseismic Deformation

Earthquakes that generate regional deformation may be recognized and catalogued. Vertical deformation can induce changes in local rates of deposition and erosion that provide evidence of a paleoearthquake, particularly in fluvial (Schumm *et al.*, 2000) and coastal environments (Carver and McCalpin, 1996). Indicators of coseismic uplift in coastal areas include shorelines, platforms, or flights of terraces above mean sea level. Formation of elevated terraces have been reported following historic earthquakes in coastal regions (e.g., Plafker

and Rubin, 1978; Matsuda *et al.*, 1978; Pirazzoli, 1991). Sequences of similar terraces and shorelines at higher elevations provide evidence of multiple episodes of tectonic uplift (Fig. 3; and Figs. 4, 5 on the Handbook CD-ROM). In shallow tropical waters, the growth of corals responds to uplift or subsidence relative to sea level and may preserve a record of vertical coseismic motion (e.g., Zachariasen *et al.*, 2000).

Tectonic subsidence induces sedimentation that can record and preserve evidence of an earthquake (Carver and McCalpin, 1996). Buried flora or fauna may provide material for dating the earthquake. For example, in the Cascadia region of northwestern USA, tsunami deposits, drowned forests, and grasslands along the coastline provided material for high precision dating of subduction zone earthquakes (e.g., Atwater *et al.*, 1995). The date of the most recent earthquake (AD 1700) was resolved from radiocarbon dating of submerged deposits, analysis of tree rings (dendroseismology), and historic accounts of tsunami recorded in Japan (Nelson *et al.*, 1995; Satake *et al.*, 1996).

Measurement and interpretation of vertical deformation in coastal regions must be based on knowledge of sea level at the time of uplift. Sea level was 100–150 m below modern levels during the last glacial maximum 15 000–20 000 y BP (Lajoie, 1986). After rising rapidly in the early Holocene, sea level stabilized in the mid-Holocene. However, sea level has fluctuated slightly (± 2 m) during the late Holocene (Lajoie, 1986) and is currently at different levels in different parts of the world (Pirazzoli, 1991). Fluctuations and regional variations have been sufficiently large to complicate interpretations of coseismic uplift or subsidence in areas with low vertical deformation rates.

FIGURE 3 Photo of shorelines and wave erosion platforms along rocky coastline of San Joaquin Hills, California. The person is standing on the active erosion platform. An elevated platform intersects the sea cliff at the paleoshoreline. An older paleoshoreline forms a notch in the sea cliff near the top of the photo. The paleoshorelines were formed by tectonic uplift of the San Joaquin Hills, southern California, USA (Grant and Ballenger, 1999).

2.2.3 Ground Shaking and Secondary Effects

Surface rupture and regional deformation are considered primary effects of earthquakes because they can be directly associated with tectonic movement of specific faults. Secondary effects of earthquakes such as liquefaction, ground failure, slope failure, tsunami, and seismic seiche are induced by shaking. A history of seismic shaking is an indirect history of regional fault activity and is useful for seismic hazard assessment. If secondary effects disturb the environment, and if they are preserved, then these effects can be catalogued to develop a chronology of paleoearthquakes. The dates of shaking events may be constrained by geochronology methods.

Evidence of liquefaction, inundation by tsunami, and seismically induced ground failures may be observed in natural or artificial exposures of young sediments, or in sediment cores. Liquefaction is a loss of bearing strength that occurs when saturated cohesionless sediments are subjected to strong shaking or cyclical loading. Fluidized sediment may mobilize during liquefaction to form distinctive sedimentary or geomorphic structures such as sand blows, sand dikes and craters (see Fig. 6 on the Handbook CD-ROM; Obermeier, 1996). Ground failures such as lateral spreading, slumping, lurching, and cracking may occur in soft sediment. In submarine or lacustrine environments, deposition of turbidites (Obermeier, 1996) or mixed-layer clays (Marco *et al.*, 1996; Doig, 1998) can provide evidence of a paleoearthquake. Nonseismic events can create structures that are virtually indistinguishable from seismically deformed sediments, or seismites (Ricci Lucchi, 1995). Therefore, paleoseismologists must correlate candidate seismites over regions and rule out nontectonic origins before concluding that an earthquake occurred. For example, the widespread presence of features attributed to liquefaction and ground failure provide strong evidence of the AD 1700 Cascadia earthquake (Adams, 1990; Obermeier and Dickinson, 2000).

Earthquake ground motions often trigger slope failures. Mountainous regions with steep slopes or unstable slope materials are particularly susceptible to seismically induced slope failures. Slope failures have been responsible for many fatalities in historic earthquakes (Bolt, 1999). In seismically active regions, slope failures over large areas may be linked to paleoearthquakes. Several methods have been developed to date paleoearthquakes by measuring the age of seismically induced landslide deposits. For example, lichenometry has been applied to date seismically induced rockfalls along the Alpine fault zone, New Zealand (Bull, 1996). The criteria for determining seismic origin, and methods for dating are summarized by Jibson (1996).

2.3 Measurement of Slip

Measurement of slip, or surface displacement, across a fault yields information about the magnitude of paleoearthquakes

and the average rate of deformation. The slip rate of a fault provides an upper bound for the rate of seismic moment release (Yong and Coppersmith, 1985; WGCEP, 1995). Slip from paleoearthquakes can be used in combination with slip rate to estimate the recurrence intervals between earthquakes and to constrain the magnitude of past ruptures.

2.3.1 Slip Rates

The slip rate of a fault, V , is obtained by measuring the displacement, D , across a fault zone during time interval, T , using Eq. (1):

$$V = D/T \quad (1)$$

To measure a slip rate, a geologist must find a feature that crosses the fault, is well defined, and is datable. Such features are called *piercing lines*. The points where they intersect a fault zone are called *piercing points*. Fault slip is measured from the displacement of piercing points and deformation of piercing lines. (Fig. 7 on the Handbook CD-ROM shows a map of an excavated piercing line across the San Andreas fault.) Geological piercing lines include streams, gullies, and linear sedimentary features. Anthropogenic piercing lines include walls, row crops, rice paddy boundaries, fences, and roads. The ideal piercing line crosses the fault at a right angle, is perfectly linear, has the same trend on either side of the fault zone, and is of precisely known age. Such conditions rarely exist. Therefore, most slip rates have considerable measurement uncertainty. For example, a compilation of fault slip rates in California (Peterson and Wesnousky, 1994) shows significant uncertainty in slip rate measurements.

Uncertainty in slip rates are caused by uncertainties in measurements of displacement and in estimates of the time interval over which the displacement occurred. Aperture of measurement affects slip rates because deformation may occur beyond the main fault zone (McGill and Rubin, 1999; Rockwell *et al.*, 2002) and have only subtle effects on piercing lines (Grant and Sieh, 1993; Grant and Donnellan, 1994; Sieh, 1996). Therefore, geologically measured slip rates may provide only minimum values if measured over short apertures. For blind faults, the displacement on the fault plane must be inferred from deformation far outside the fault zone, and the resulting slip rates have even larger uncertainties.

The length and variation of time intervals between surface ruptures may affect measurements of slip rate or slip per event. For faults that do not creep, surface displacements are generated episodically by earthquakes. If the slip rate of a fault is low and the average time between surface ruptures is long—the case for most faults—measurements of slip rate may be significantly greater or less than the average rate over multiple rupture cycles. It is generally assumed that slip rate is constant over the interval of measurement, but for most faults there are insufficient data to test this assumption. Geomorphic analysis of normal fault scarps in the Basin and Range province, USA,

FIGURE 4 Idealized sequence of two normal faulting events and formation of a colluvial wedge, as exposed in trench excavations. (From Lettis and Kelson, 2000.) (a) First surface faulting event; (b) first colluvial wedge (1) and soil formation; (c) second surface faulting event; (d) second colluvial wedge (2) and soil formation.

FIGURE 5 Summed Gaussian probability density functions for measured surficial offsets along the Garlock fault (a) (from McGill and Sieh, 1991), and from the 1992 $M_{7.3}$ Landers earthquake on the Emerson fault, California (b). Each peak in the Garlock distribution was originally interpreted to be the result of displacement from a separate surface rupture. Measurements from the Landers earthquake show that surficial offset from a single earthquake can have a multimodal frequency distribution. (From McGill and Rubin, 1999.)

reveals significant temporal variation in slip rates for several faults (Slemmons, 1995).

2.3.2 Slip per Event

The amount of slip per event can be used to estimate the magnitude of previous earthquakes and the time between earthquakes (if the average slip rate is known). The distribution of slip may also reveal the location of segment boundaries, and areas of characteristic slip, if any are present (Ward, 1997).

To measure slip per paleoearthquake, it is necessary to identify a piercing line that has been displaced by a known number of earthquakes. Ideally, this is done by measuring the displacement of a piercing line of known age in an area where the dates of individual surface ruptures are well constrained. For normal and reverse faults, the vertical component of displacement can be measured directly by excavating a trench across the scarp (Fig. 4) because material deposited by collapse or decay of a vertical scarp typically buries and preserves evidence of the rupture. Changes in slope or height of a scarp may indicate multiple ruptures. Variation in the amount of lateral displacement of piercing lines along a strike-slip fault can indicate multiple surface ruptures. In coastal areas, the vertical component of displacement can be measured from elevated marine shorelines (see Fig. 5 on the Handbook CD-ROM) (Matsuda *et al.*, 1978; Plafker and Rubin, 1978). For strike-slip faults, the best measurements are obtained from three-dimensional excavation using multiple trenches (Weldon *et al.*, 1996). An alternate, but less-reliable, method is to measure displacement of surficial

features such as laterally offset channels. The total number of earthquakes is then inferred from peaks in the frequency distribution of measurements (Fig. 5), or by the assumption of constant (or “characteristic”) slip per event (see Section 3.2). Uncertainty in the resulting slip per event measurements is unconstrained (see Fig. 10 on the Handbook CD-ROM).

2.4 Magnitude of Paleoearthquakes

In general, the effects of an earthquake are proportional to its size (Slemmons and dePolo, 1986). Therefore, the amount of slip, tectonic deformation, or secondary effects preserved in the paleoseismic record helps to constrain the size of a paleoseismic event. The magnitude of paleoearthquakes can be estimated from measurements of slip per event or from rupture length inferred by correlating dates of paleoseismic events at different sites.

Empirical regression relationships between historic earthquake magnitude and rupture length, average slip, or maximum slip (Wells and Coppersmith, 1994) can be applied to estimate the magnitude of paleoearthquakes (Table 2). Hemphill-Haley and Weldon (1999) developed empirical relationships specifically for estimating magnitude from paleoseismic measurements of slip. Their method provides uncertainties based on the number of measurements and percentage of rupture length sampled.

For faults with chronologies of earthquakes from multiple paleoseismic investigations, surface rupture lengths can be

TABLE 2 Hierarchical Classification of Paleoseismic Features (Modified from McCalpin, 1996)

	On Fault Coseismic	On Fault Postseismic	Off Fault Coseismic	Off Fault Postseismic
<i>Primary</i>				
Geomorphic expression	• Fault scarps • Fissures • Folds • Moletracks • Pressure ridges	• Colluvial aprons • Afterslip contribution	• Tilted surfaces • Uplifted shorelines • Drowned shorelines	• Tectonic alluvial terraces • Afterslip contribution
Stratigraphic expression	• Faulted strata • Folded strata	• Colluvial wedge • Fissure fill • Unconformity	• Tsunami deposits	
Abundance of similar nonseismic features	Few	Few	Some	Common
<i>Secondary</i>				
Geomorphic expression	• Sand blows • Landslides • Disturbed trees	• Retrogressive landslides	• Sand blows • Landslides • Fissures • Subsidence from compaction	• Retrogressive landslides
Stratigraphic expression	• Sand dikes	• Rapidly deposited lake or estuarine sediments	• Sand dikes • Filled craters • Soft-sediment deformation • Turbidites	• Rapidly deposited lake or estuarine sediments
Abundance of similar nonseismic features	Some	Very common	Some	Very common

estimated by assuming that ruptures with overlapping time windows occurred at the same time (see Section 3.4). However, there are large uncertainties in correlating ruptures between paleoseismic investigation sites, so the inferred rupture length and resulting magnitudes are poorly constrained. Segmentation models (see Section 3.1) have also been applied to estimate paleoearthquake rupture length and magnitude.

3. Models and Uncertainty

Paleoseismic data provide information about earthquakes over scales of time and magnitude that are useful for seismic hazard assessment and essential for understanding the long-term rupture patterns of faults. Therefore, paleoseismic data have been influential in the development and testing of models that describe fault behavior over multiple rupture cycles, and in forecasting earthquakes. This section describes models that depend critically on observations of paleoearthquakes, and discusses uncertainty in paleoseismic data.

3.1 Segmentation

Segmentation models assume that faults are divided into discrete, identifiable sections that behave distinctively over multiple rupture cycles (e.g., Schwartz and Coppersmith, 1986; Slemmons, 1995). Segment boundaries are thought to control the termination and initiation of fault ruptures and therefore limit the magnitude and rupture pattern of an earthquake. Fault segments are defined based on structural discontinuities, changes in strike, and rheology (Allen, 1968) as well as by paleoseismic data (Chapter 29 by Sibson; Schwartz and Coppersmith, 1984; Sieh and Jahns, 1984; WGCEP, 1988, 1990; Schwartz and Sibson, 1989).

Segmentation models are attractive because they simplify fault behavior. For example, in seismic hazard assessment it is desirable to estimate the size of the largest earthquake that can occur on a fault (Yeats *et al.*, 1997). The maximum magnitude earthquake can be estimated from empirical relationships (Table 3) and the estimated length of maximum rupture (Wells and Coppersmith, 1994). This would be either the maximum length of the fault, or of the segment. Similarly, the size of a paleoearthquake can be estimated by assuming that the entire segment ruptured.

Testing of segment models requires defining segments and then observing multiple ruptures. This would take decades to centuries for the fastest slipping faults, and thousands of years for most faults. Therefore, few segment models have been tested against rupture patterns of historic earthquakes (Sieh, 1996). Results are mixed. For example, two large earthquakes on strike-slip faults in the western US (*M*7 1989 Loma Prieta and *M*7.3 1992 Landers) propagated through previously identified segment or fault boundaries (WGCEP, 1990; Sieh *et al.*, 1993). However, several historic ruptures of normal faults in the Great Basin have terminated at or near fault

discontinuities (Zhang *et al.*, 1999). More observations are needed to test segmentation hypotheses and their utility for seismic hazard assessment.

3.2 Characteristic Earthquakes

The characteristic earthquake model (Schwartz and Coppersmith, 1984) is probably the most influential model of fault rupture and earthquake recurrence developed from paleoseismic data. The basic tenet of the model is that most surface slip on a fault occurs in *characteristic earthquakes*. Characteristic earthquakes are the result of *characteristic slip*. Figure 6c illustrates the concept of characteristic slip; at a specific location along a fault, the displacement (slip) is the same in successive characteristic earthquakes. This implies that characteristic earthquakes have similar rupture patterns and that a fault can be divided into segments that behave characteristically. Each segment would have a distinctive or “characteristic” rupture pattern and magnitude. Characteristic slip requires variable slip rate along a fault to account for different amounts of displacement.

If characteristic slip occurs on a fault, then most seismic moment is released by repetition of characteristic earthquakes of approximately the same magnitude. Characteristic slip causes a kink in the frequency magnitude relationship, known as characteristic recurrence (Fig. 7), due to the dominance of relatively large magnitude characteristic earthquakes (Schwartz and Coppersmith, 1984). The characteristic recurrence curve appears to fit the frequency–magnitude distribution for some faults (Wesnousky, 1994) but does not fit global seismicity rates as well as other models (Kagan, 1993).

FIGURE 6 Schematic representations of (a) variable slip, (b) uniform slip, (c) characteristic slip, (d) overlap, and (e) coupled slip models. (From Schwartz and Coppersmith, 1984; Berryman and Beanland, 1991. Reprinted from McCalpin, 1996.)

The characteristic earthquake model is convenient for seismic hazard assessment because it assumes that faults can be divided into identifiable segments that rupture with characteristic slip and recurrence. Many studies of active faults

have focused on identifying characteristic rupture segments of faults and their properties (e.g., Wesnousky, 1986; Peterson and Wesnousky, 1994; WGCEP 1988, 1990, 1995). For example, earthquake forecasts for the San Andreas fault

FIGURE 7 Characteristic recurrence model for cumulative frequency-magnitude distribution of seismicity on a specific fault. (From Schwartz and Coppersmith, 1984.)

have been based on a combination of segmentation, time-predictable, and characteristic earthquake models. The Parkfield segment of the San Andreas fault was predicted to break before 1993 with repetition of characteristic earthquake (Bakun and Lindh, 1985; WGCEP, 1988). To date, the expected Parkfield earthquake has not occurred, so the pattern of rupture cannot be tested against the models. The Working Group on California Earthquake Probabilities (WGCEP, 1988, 1990, 1995) divided the San Andreas fault into characteristic segments and issued probabilistic rupture forecasts. In 1989, the $M7$ Loma Prieta earthquake occurred on portions of two segments defined prior to the earthquake (WGCEP, 1990) rather than on a single segment. Hecker and Schwartz (1994) analyzed paleoseismic data for many faults and concluded that most faults exhibit characteristic slip. However, recent paleoseismic studies of the San Andreas fault reveal complexity in spatial and temporal rupture patterns that was not evident when the characteristic earthquake model was first proposed (Grant, 1996). Debate about the applicability of the characteristic earthquake model for forecasting earthquakes is likely to continue (Yeats *et al.*, 1997; Yeats, 2001).

3.3 Time Predictable and Recurrence Models

Recurrence time, T_r , is the time interval between successive ruptures of the same fault. T_r is useful for describing the

seismic parameters of an active fault (see Chapter 65 by Somerville and Moriwaki). Paleoseismic investigations are the main source of data for measuring or estimating T_r . Individual recurrence times or average recurrence intervals (the average time interval between ruptures) can be measured directly by dating successive surface ruptures. For well-studied faults such as the San Andreas, average recurrence intervals and their variance are available for several locations along the fault (e.g., WGCEP, 1995, 1999). For most faults, there is insufficient information to describe variability in recurrence times.

If dates of paleoearthquakes are not available, recurrence time may be estimated for a fault using the relationship:

$$T_r = D/V \quad (2)$$

where V is the slip rate and D is average displacement (slip). Assuming the slip rate is constant over the period of observation and there is no creep, then the recurrence time is a linear function of displacement. If displacement occurs in constant-size (characteristic) earthquakes, then the recurrence time can be “predicted”. Thus Eq. (2) is referred to as the time-predictable model, after Shimazaki and Nakata (1980) who developed it from observations of uplifted coastal terraces in Japan. If the characteristic earthquake model and time-predictable model are combined, the result is a periodic recurrence model.

Analysis of historic earthquakes and paleoseismic data from several regions shows that occurrence of large earthquakes is irregular (Goes, 1996). Surface ruptures of the San Andreas fault have been proposed to occur irregularly (Jacoby *et al.*, 1988; Sieh *et al.*, 1989) or in clusters (Grant and Sieh, 1994). Temporal and/or spatial clustering of surface ruptures has also been proposed to describe surface ruptures in the Basin and Range (Wallace, 1981; Slemmons, 1995; McCalpin, 1996) and eastern California shear zone, USA (Rockwell *et al.*, 2000). Historic ruptures of the North Anatolian fault zone in Turkey and patterns of late Holocene seismicity in Iran suggest that seismicity may be triggered by stress shadows from previous ruptures to form temporal clusters or sequences of damaging earthquakes (Stein *et al.*, 1997; Berberian and Yeats, 1999). For most faults, the number of documented paleoearthquakes and the precision of their dates are inadequate to test hypotheses of clustered or triggered earthquakes. Larger paleoseismic data sets are needed to conduct statistically significant tests of recurrence models.

3.4 Rupture Patterns in Space and Time

Patterns of fault rupture in space and time yield insights about the physics of faulting (Ward, 1997) and provide templates for estimating the location and size of future earthquakes. Several models of fault behavior (shown in Fig. 6) are based on multiple paleoseismic measurements of slip at different sites along

Timing of moderate to large surface rupturing events on Mojave black faults

FIGURE 8 Compilation of rupture history for several faults in the Mojave desert, California, USA. The sequence suggests regional temporal clustering of paleoearthquakes. (From Rockwell *et al.*, 2000.)

a fault. The variable slip model (Fig. 6a) assumes a constant slip rate along the fault with variable displacement per event at a location, and variable earthquake size. The uniform slip model (Fig. 6b) is similar to the characteristic slip model (Fig. 6c) because both assume constant-size displacement at a location. The slip rate is constant along the fault in the uniform slip model. Therefore, a range of earthquake sizes is required to account for sections of fault with large or small slip per event. The overlap model (Fig. 6d) assumes constant displacement per event at a point (characteristic slip), variable slip rate along the fault, and repetition of constant size large earthquakes. Finally, the coupled model (Fig. 6e) is a uniform slip model coupled with a segmentation model.

Spatial and temporal patterns of fault rupture can be analyzed by plotting the dates of paleoearthquakes on a space–time diagram. Figures 8 and 9 show examples from a group of faults that ruptured in the 1992 Landers earthquake, and the southern San Andreas fault. Uncertainty in dates ranges from decades to more than a thousand years. Paleoearthquakes at adjacent sites with overlapping dates could have been the

same rupture, or separate ruptures that are indistinguishable within the uncertainty. Additional dates of paleoearthquakes would provide better constraints on the locations and magnitudes of past ruptures.

3.5 Uncertainty in Paleoseismic Data

The quality and reliability of paleoseismic data are affected by the investigation method, the characteristics of the study site, and the perspective of the investigator. Many paleoseismic studies are destructive to the study site, so the data cannot be reproduced or compared with a control. Therefore, each paleoseismic publication becomes a repository of data that will be interpreted by scientists who will not be able to evaluate it first-hand. Collection of paleoseismic data requires recognition and interpretation of complex patterns in the geologic record and landscape. Therefore, some interpretation is automatically convolved with the data, and no deconvolution algorithm can be applied after the data are published. Paleoseismologists have developed several methods to reduce

FIGURE 9 Space-time rupture correlation diagram for paleoseismic sites along the southern San Andreas fault, California, USA. Vertical lines show age limits for paleoearthquakes at each site. Horizontal lines represent ruptures, based on proposed correlations between sites. (From Arrowsmith *et al.*, 1997. Modified from Grant and Sieh, 1994 and other sources.)

subjectivity and standardize uncertainty in their data. Fault exposures are generally documented with photographs as well as logs. Photos are objective records, devoid of interpretation. “Trench parties” are held to allow reviewers to examine primary field data prior to publication. When possible, care is taken to fill excavations so that they can be reopened at a later date. Uncertainty in data collection and field interpretations are often reported qualitatively. For example, Sieh (1978) and McGill and Sieh (1991) reported the apparent “quality” of their measurements of offset streams. Paleoseismologists may report high quality measurements with “high confidence”. Such assessments are qualitative, and should not be confused with statistical confidence intervals.

4. Applications

Paleoseismic data are used for seismic source characterization in hazard assessment and mitigation (see Chapter 65 by

Somerville and Moriawaki). Probabilistic seismic hazard assessment incorporates information on fault location and geometry, slip rates, recurrence intervals, dates of previous ruptures, and maximum earthquakes. Maximum earthquakes are estimated from segmentation models, slip per event, and lengths of previous ruptures. Deterministic hazard assessments use paleoseismic data to develop earthquake scenarios including rupture location, magnitude and surface displacement. Earthquake scenarios are used to estimate expected damage for emergency response planning. Surface rupture hazard can be mitigated by identifying fault zones that are most likely to rupture and restricting land uses within such zones. Paleoseismic investigations provide data on the recency and frequency of fault rupture, as well as the type and width of surface rupture. This information can be used to classify fault zones according to rupture potential and expected displacement in future earthquakes. Critical structures can be sited to avoid rupture hazard zones, or designed to accommodate expected displacement.

5. Future Directions

Paleoseismology is a young science that focuses on understanding the long-term patterns of large earthquakes. Paleoseismic data can be applied toward understanding the behavior of faults, estimating the potential for large earthquakes to occur in populated areas, and for mitigating seismic hazard. As populations increase in seismically active areas, many paleoseismologists are moving toward predictive or applied work in seismic hazard assessment. Establishment of digital databases and standard formats for paleoseismic data allows better integration with more quantitative fields of seismology and earthquake engineering. Investigations of active faults are being extended to offshore areas (e.g., Goldfinger and Nelson, 2000) and paleoseismic data are being compiled for the World Map of Active Faults under the International Lithosphere Program. As paleoseismology matures, it is likely to play an increasingly important role in seismology and society.

Using Earthquakes for Continental Tectonic Geology

James A. Jackson

University of Cambridge, Cambridge, United Kingdom

1. Introduction

Seismology contributes to tectonic and structural geology mostly through earthquake source studies or, more specifically, through being able to estimate the location, geometry and size of slip on faults. Earthquake seismology made a fundamental contribution to the discovery and confirmation of plate tectonics through studies that used fault plane solutions to demonstrate plate rigidity (McKenzie and Parker, 1967) and the nature of plate boundaries (Sykes, 1967; Isacks *et al.*, 1968). It is notable how quickly these studies appeared after the installation of the World Wide Standardized Seismograph Network (WWSSN) in the early 1960s made reliable determinations of focal mechanisms possible. In the 1970s earthquake seismology was responsible for important advances in understanding large-scale continental tectonics (e.g., McKenzie, 1972; Molnar and Tapponnier, 1975) but had little influence on more detailed structural geology on the continents until about the 1980s, for two reasons, which are linked. Firstly, the continents deform in ways that are more complicated than the oceans, with earthquakes and faults distributed over wide areas and not confined to the narrow plate boundaries that typify the oceans. There are indeed patterns in the active faulting in such continental regions, but they were not easy to recognize with the relatively few earthquake focal mechanisms available soon after the installation of the WWSSN. Secondly, earthquake source seismology could not contribute much to debates in structural geology through the 1970s, because it was too inaccurate. In particular, first motion fault plane solutions were rarely well-constrained in orientation, and routinely reported focal depths based on teleseismic arrival time data were notoriously unreliable, unable to tell whether an earthquake was in the crust or the mantle, let alone within the crystalline basement or sedimentary cover.

Two advances helped to increase the impact of seismology on structural geology by the late 1970s. The first was the

installation of many dense local seismograph networks, often temporary and designed to monitor aftershocks, which greatly improved knowledge of focal depth distributions outside the few areas where permanent dense networks already existed. The second was the development of synthetic seismogram techniques that allowed much more accurate determination of earthquake source parameters from teleseismic waveforms themselves, rather than from just the arrival times and first motion polarities (see Appendix on the Handbook). For earthquakes larger than $M_w \sim 5.5$ it became possible, under favorable conditions, to estimate fault geometry (strike, dip, rake) to within $5\text{--}15^\circ$, centroid depth to within $\sim \pm 3$ km, and seismic moment to within 10–20%.

As more abundant and better quality earthquake data became available on the continents the natural advantages of seismology could then be exploited

- Earthquake source seismology could provide information about the fault geometry underground which, when combined with surface observations, could give an overall three-dimensional image of the fault.
- Faults could be studied as they moved, in their original orientation, unaffected by uplift, rotation or tilting.
- Large areas could be investigated quickly to look for patterns of fault movement, in the sure knowledge that faults which are seismically active now are all part of the same deformational episode.

With these abilities earthquake seismology had something new to offer. Hitherto, structural and tectonic geology had necessarily been based on field or seismic reflection studies of faults that are now inactive. Many of these old structures are no longer in their original orientation, and demonstrating that old faults over a wide region had been active simultaneously was a major effort, if it was possible at all. Moreover, comparative studies between inactive regions were difficult, limited by the area any field geologist could reasonably address.

Earthquake source studies have certainly not supplanted or made redundant the older field- and seismic reflection-based methods of structural investigation, each of which have their own obvious advantages. However, by offering insights that were simply unobtainable by other means, earthquake seismology has profoundly influenced thoughts and concepts in tectonic geology over the last 20 years.

This review summarizes some of the major contributions of earthquake seismology to debates in structural geology and continental tectonics, some of which are still controversial. To keep a perspective, we should realize that earthquake seismology provides a tool that is most effective when used with other tools. Balanced studies of active tectonic processes combine seismological information with data from any other sources that are available, especially surface observations of geology, geomorphology, and geodesy (e.g., Yeats *et al.*, 1997). However, in order to highlight the contribution of earthquake seismology, I have deliberately selected examples illustrating processes that would have been extremely difficult or impossible to demonstrate from nonseismological observations alone or from the study of inactive geological structures. I invite the reader to keep in mind the question: "Could we have discovered that without the earthquakes?" Most of the examples quoted come from the Alpine–Himalayan orogenic belt, partly because I am most familiar with that region but also because it is so large, so active, and provides such a rich store to plunder. This is not a serious bias: the processes illustrated here are general and can often be recognized in the earthquake record of a number of different places.

2. Scale and the Seismogenic Layer

2.1 Focal Depth Distributions and Strength

Once well-determined focal depths were more abundant, it became clear that the confinement of continental seismicity to the upper half of the crust, which had been known in California for some time, was a common global phenomenon (e.g., Chen and Molnar, 1983). In most areas the lower continental crust is virtually aseismic. This pattern is usually interpreted in terms of a temperature-related rheology (e.g., Scholz, 1988), with the implication that the upper crust has greater long- and short-term strength than the lower crust. Until recently, it was thought that occasional rare earthquakes in the uppermost continental mantle beneath the Moho may indicate another strength contrast between the crust and the mantle related to composition (Chen and Molnar, 1983; Chen, 1988), giving rise to a popular view of continental strength profiles in which a weak lower crust is sandwiched between relatively strong layers in the upper crust and mantle. Although it has been influential for 20 years, this view has been challenged by Maggi *et al.* (2000a,b). With the help of better-determined Moho depths from teleseismic receiver functions,

they find no evidence for significant seismicity in the continental mantle, though in places earthquakes occur throughout the continental crust down to Moho depths. They also found that variations in the seismogenic thickness (T_s) correlate with variations in the effective elastic thickness (T_e), both of them having similar values, though T_e is usually the smaller of the two (see also McKenzie and Fairhead, 1997). These observations suggest that, at least in some places, the lower crust is stronger than the mantle beneath the Moho, not weaker. If correct, this new view has important implications. In particular, the strength of the continental lithosphere is likely to be contained within the seismogenic layer, with variations in the thickness of this strong layer determining the heights of the mountain ranges it can support. To explain the revised earthquake depth distribution on the continents some other effect is needed in addition to temperature: Maggi *et al.* (2000a,b) suggest that the aseismic nature of the continental mantle and the lower crustal seismicity beneath some shields are probably related to their water contents.

Though the rheological implications of the earthquake focal depth distribution are profound, the more fundamental impact on structural geological thinking is probably the implication of scale. The thickness of the seismogenic upper crust is typically 10–20 km and imposes a scale on all structural observations. Large faults are those with dimensions comparable to that thickness and may rupture the entire layer in earthquakes. Small faults are those that can be accommodated entirely within the seismogenic layer. This framework gives an objective criterion for distinguishing "big" faults and earthquakes from "small" ones. Seismologists have been aware of this distinction in the scaling properties of earthquakes for some time (e.g., Shimazaki, 1981; Scholz, 1982). The geological consequences of a fundamental break in scale at the thickness of the seismogenic layer fall into two main areas.

2.2 Organization of Strain and Faulting

Most maps showing fault plane solutions of moderate-to-large ($M_w > 5.5$) shallow earthquakes on the continents are remarkable for the regular patterns they display (e.g., Figs. 1 and 2 and Color Plate 10), with focal mechanisms uniform or smoothly varying in orientation over very wide regions, with few anomalies. The organization of large active faults into subparallel or regular patterns over areas that are large compared with the lithosphere thickness is an important characteristic of distributed deformation on the continents. It is the reason why the influential early studies of active continental tectonics in the Alpine–Himalayan belt by McKenzie (1972) and Molnar and Tapponnier (1975) were not misled by the relatively sparse focal mechanism data available to them at the time. It is also the organization of the strain fields at long wavelengths that suggests the origin of the large-scale driving forces on the edges of or within the deforming

FIGURE 1 Fault plane solutions in the Iranian plateau. Black focal spheres are those constrained by body wave modeling. Dark gray spheres are Harvard CMT solutions for additional earthquakes with $M_w \geq 5.3$ and with more than 70% double-couple component (see Appendix on the attached Handbook CD). Light-gray focal spheres are other earthquakes whose mechanisms are based on long-period first-motion polarities. Main active fault trends are from Berberian and Yeats (1999). Important patterns include: (1) reverse faulting parallel to the topographic trend of the Zagros mountains (Z); (2) NW–SE right-lateral faulting along the NE edge of the northern Zagros (near 34°N 48°E), with slip vectors orthogonal to the nearby thrusts; (3) and N–S right-lateral faulting both east and west of the Dasht-e-Lut (L), changing to E–W left-lateral faulting further north; (4) NW–SE trending reverse faults throughout eastern Iran.

FIGURE 2 Fault plane solutions and active faults in and around Tibet, adapted from Molnar and Lyon-Caen (1989). Black focal spheres are those constrained by body wave modeling. Gray focal spheres are Harvard CMT solutions for additional earthquakes with $M_w \geq 5.3$ and with more than 70% double-couple component (see Appendix on the attached Handbook CD). Important patterns here include: (1) low-angle thrust faults along the Himalayan thrust front (HFT) with divergent slip vectors following the arc of the Himalaya (H); (2) N–S normal faulting, particularly in southern Tibet south of a band of right-lateral faulting running east from the Karakoram Fault (K); (3) a subparallel system of left-lateral faults in eastern Tibet including the Haiyuan (HF), Kun Lun (KL) and Xian Shuihe (X) faults; (4) NW–SE reverse-fault solutions near the Qaidam basin (Q). The Altyn Tagh fault is marked ATF.

regions (e.g., England and McKenzie, 1982; Vilotte *et al.*, 1982).

Such organization is not always seen in small faults and small earthquakes. The focal mechanisms of many small earthquakes are often similar to those of the nearby large ones, but anomalies are quite common, particularly in aftershock sequences, where normal faulting aftershocks can follow reverse faulting mainshocks (e.g., Whitcomb *et al.*, 1973) and vice versa (e.g., Lyon-Caen *et al.*, 1988). Some of these anomalies are no doubt related to local strain inhomogeneities around the main faults, caused by irregularities in shape, slip distribution or fault terminations, and are also seen in minor coseismic ruptures at the surface. Examples include normal faulting in hanging wall anticlines above thrusts (Yielding *et al.*, 1981; Philip *et al.*, 1992) and minor normal faulting perpendicular to major normal faults where the large ones are arranged in en echelon steps or relays (e.g., Jackson *et al.*, 1982). Such instances produce little confusion when the configuration of the larger faults is already known, but small faults on their own may not be a reliable guide to the regional strain pattern. An awareness of the size of the fault compared with the thickness of the seismogenic layer is essential when assessing its tectonic significance.

2.3 Segmentation and Basin Width

The thickness of the seismogenic layer also appears to influence the maximum size of some structures that form within it. This is seen best in the segmentation of normal faults and width of graben in extensional provinces.

The normal fault systems that bound continental rifts are commonly segmented, stepping en echelon or changing the polarity of half graben along strike (e.g., Rosendahl *et al.*, 1986; Crone and Haller, 1991; Roberts and Jackson, 1991). The maximum segment length is a characteristic of any region and appears to correlate with the seismogenic thickness (T_s), being typically ~ 20 – 25 km long where $T_s \approx 15$ km (Jackson and White, 1989; Wallace, 1989) but increasing to 60–100 km in parts of East Africa (Fig. 3) where, unusually, T_s reaches 30–35 km (Jackson and Blenkinsop, 1997; Foster *et al.*, 1997). Fault-bounded topography within the elastic upper crust is supported by stresses that depend on the wavelength and height of the topographic contrasts as well as on the layer thickness. Thus the seismogenic thickness can be expected to control the maximum width of coherently tilted blocks or half graben if the shear stresses acting on the faults are not to exceed the typical range of 1–10 MPa stress drops seen in earthquakes (Jackson and White, 1989; Foster and Nimmo, 1996). Observations support such a correlation, with maximum half-graben widths of typically 10–25 km where $T_s \approx 15$ km but much greater widths of up to 60 km in those parts of East Africa where $T_s \approx 30$ – 35 km (Jackson and Blenkinsop, 1993). Thus the thickness of the seismogenic layer seems to control both the maximum width of extensional

FIGURE 3 A comparison of normal fault segmentation in parts of Tanzania (Foster *et al.*, 1997) and Malawi (Jackson and Blenkinsop, 1997) where earthquakes occur to depths of 25–30 km, and central Greece, where earthquakes are limited to the upper 10–15 km of the crust. In Greece, maximum segment lengths are ~ 25 km, whereas in Tanzania and Malawi they reach lengths of 60–100 km. These examples have been chosen because the author is familiar with all of them in the field, and has used the same criteria for identifying segment terminations in each case.

graben and the continuity of the faults that bound them (Jackson and White, 1989; Hayward and Ebinger, 1996). This influence arises because the thickness of the seismogenic layer controls the scale of the tilting, limiting the displacement on the bounding faults, and thus limiting their length through a displacement–length scaling relationship for faults (Scholz and Contreras, 1998).

It is possible that similar relationships exist for reverse and strike-slip faults. Segmentation can be seen in both types, both in co-seismic surface ruptures and in the body waveforms of earthquakes (e.g., Yielding 1985; Haessler *et al.*, 1992; Sieh *et al.*, 1993; Wald and Heaton, 1994; Berberian *et al.*, 1999). However, the topography associated with strike-slip and particularly with blind reverse faults is often less clear than for normal faults, making objective identification of segment boundaries more difficult in the absence of earthquakes.

3. Fault Dips

3.1 Normal Faults

Ever since the discovery that many continental sedimentary basins are formed by extension (McKenzie, 1978a), there has been intense interest in the geometry and kinematics of normal faulting on the continents. A great variety of normal faulting styles have been seen, or inferred, from geological outcrops or seismic reflection surveys, including steep planar faults,

strongly listric faults that become virtually flat within the upper crust, and very low-angle faults dipping at less than $\sim 20^\circ$ (e.g., Wernicke and Burchfiel, 1982). Observations of large normal faults that move in earthquakes show a very simple pattern of dips that are apparently restricted to a range of about $30\text{--}65^\circ$ (Fig. 4a), whether determined by first motion polarities or by body wave modeling (Jackson, 1987; Jackson and White, 1989; Thatcher and Hill, 1991). For coseismic ruptures that break the Earth's surface, the agreement between the centroid dip and the slip vector measured at outcrop makes significant curvature between the surface and the base of the seismogenic layer unlikely (e.g., Jackson and White, 1989), an inference that can be confirmed in some cases by more sophisticated body wave modeling (Braunmiller and Nábělek, 1996) or by coseismic elevation changes (Stein and Barrientos, 1985). It seems probable that the great majority of large, seismically active normal faults on the continents are roughly planar throughout the seismogenic layer, dipping typically at $45 \pm 15^\circ$. The spread in observed dips may be related to the rotation of these faults about a horizontal axis as they move (Jackson and White, 1989), and is entirely compatible with simple views of fault mechanics involving Byerlee friction, vertical and horizontal principal stress orientations, and pore fluid pressures up to, but not exceeding, the least principal stress (e.g., Sibson, 1994). Genuine listric (concave-up) normal faults are common within thick sedimentary sequences, often

flattening onto weak horizons of overpressured shale or salt, but they appear not to generate earthquakes when they move. Generalizations of this sort have proved useful in hydrocarbon exploration, as they give some indication of what to expect, depending on whether the large faults of interest are in crystalline basement or in thick sediment sequences containing decoupling horizons.

By contrast, normal faulting earthquakes with dips less than 20° , corresponding to slip on very low-angle "detachment" surfaces of the sort inferred to have been active in the Miocene metamorphic core complexes of the western North America (Wernicke, 1981), are rare (e.g., Abers, 1991). Reconciling this observation with the proposed origin of these currently shallow-dipping surfaces remains controversial (e.g., Jackson, 1987; Wernicke, 1995), with suggestions including the rotation of the surfaces during movement by extreme flexure or lower-crustal flow (e.g., Buck, 1988; Wernicke and Axen, 1988; McKenzie *et al.*, 2000). The point to make here is simply that this subject would not be controversial at all were it not for the observations from earthquakes.

3.2 Thrusts and Reverse Faults

Earthquakes on active thrust and reverse faults on the continents show a much wider range of dips than do active normal faults. Perhaps the most important point here is that centroid

FIGURE 4 (a) Histogram of nodal plane dips for normal faulting earthquakes in the Aegean extension province between $34\text{--}44^\circ\text{N}$ $20\text{--}32^\circ\text{E}$. Dips from mechanisms constrained by body wave modeling are in black. In white are dips from Harvard CMT solutions for additional earthquakes with $M_w \geq 5.3$ and with more than 70% double-couple component (see Appendix on the attached Handbook CD). The histogram contains only mechanisms with rakes in the range of -60° to -120° (corresponding to slip vectors within $\pm 30^\circ$ of pure dip slip), and in each case both nodal planes have been included. The concentration between 30° and 65° is a global feature, as is the rarity or absence of very-low-angle dips of less than $\sim 20^\circ$ (Jackson and White, 1989). (b) Histogram of nodal plane dips for reverse or thrust-faulting earthquakes within the Iranian plateau ($26\text{--}36^\circ\text{N}$, $46\text{--}62^\circ\text{E}$) (region of Fig. 1). Selection of earthquakes is on the same criteria as in (a), but with the rake range $+60^\circ$ to $+120^\circ$. Dips from body-wave mechanisms are in black, additional earthquakes with Harvard CMT mechanisms are in gray, and other earthquakes with first motion mechanisms are in white. The most common dips are in the range $25\text{--}70^\circ$, similar to those of normal faults in (a). In this case, however, the lack of low-angle dips is not a global feature, as can be seen in Figure 2 and Color Plate 10.

depths are typically in the range 10–20 km, which clearly implies faulting in “basement” rocks in most regions. There is much interest in how such earthquakes relate to classical concepts of ‘thin-skinned’ fold-and-thrust belts, in which sediments are decoupled and thrust over an apparently undeformed basement, as described, for example, in the foreland of the Rocky Mountains (Bally *et al.*, 1966). In these thin-skinned systems the thrusts typically follow incompetent horizons at shallow dips (“flats”), cutting up through more competent ones at a steeper angle on reverse faults or “ramps.”

Low angle (10–20° dip) thrusts are seen to move in earthquakes on the continents, but are relatively rare (see below). In Asia they occur particularly along the southern margin of the Himalaya (e.g., Molnar and Lyon-Caen, 1989) and on both sides of the Greater Caucasus (Fig. 2 and Color Plate 10). In the case of the Himalaya, such earthquakes occur at depths of 10–15 km, but with epicenters 50–100 km north of the surface outcrop of thrusts in the deforming foreland basin. Particularly rapid uplift occurs in the epicentral regions of these earthquakes (Jackson and Bilham, 1994), and one interpretation is that they represent slip on a basement fault (or ramp) dipping 10–20° that becomes flatter (<10° dip) at shallower depth and is currently aseismic (e.g., Ni and Barazangi, 1984; Molnar and Lyon-Caen, 1988). There is some debate about the precise nature of the very-low-angle surface or decoupling horizon at shallow depths, the degree to which it is locked or creeps aseismically, and how it moves in occasional great earthquakes (e.g., Seeber and Armbruster, 1981; Molnar and Lyon-Caen, 1988; Yeats *et al.*, 1997). But the elements of the “ramp-and-flat” geometry of classic fold-and-thrust belts are at least recognizable, and the basement beneath the shallow decoupling horizon may be relatively undeformed.

More problematic are the earthquakes on relatively steep (30–60° dip) reverse faults, which are actually more common on the continents than earthquakes on gently dipping (10–20°) thrusts (e.g., Jackson and Fitch, 1981; Molnar and Chen, 1982; Triep *et al.*, 1995; Sibson and Xie, 1998). Steep reverse-faulting earthquakes with centroids at depths of 5–20 km occur in many parts of central Asia, Iran (Fig. 4b), southern California, the eastern margin of the Andes, New Guinea and in many intraplate settings. In several places, such as the Zagros of Iran (Jackson and Fitch, 1981; Berberian, 1995), Papua New Guinea (Abers and McCaffrey, 1988) and the Peruvian Andes (Suarez *et al.*, 1983), these seismogenic reverse faults rarely cut the surface, and there is evidence that the steep basement faults are decoupled from their overlying deforming sediments by a weak horizon, such as salt or shale. In these examples, although the deformation in sediments at shallow depths is probably not connected to the basement by through-going faults, it is misleading to think of the system as “thin-skinned” in the same sense as it was in the Rockies or Appalachians, as the basement beneath the sediments is clearly deforming as well. In other places, the steep reverse faults reach, or nearly reach, the surface in earthquakes, often

forming anticlines in their hanging walls. In several instances a combination of surface observations, seismology, and sometimes geodesy can be used to demonstrate that these faults remain steep and approximately planar throughout the seismogenic upper crust (e.g., Whitcomb *et al.*, 1973; Yielding *et al.*, 1981; Haessler *et al.*, 1992; Wald *et al.*, 1996).

An important issue with all these steep reverse faults is what happens below the base of the seismogenic zone. It is possible that the steep faults merge with a low-angle, aseismic decoupling horizon within the plastic lower crust (e.g., Namson and Davis, 1988; Shaw and Suppe, 1994). In this view, the ramp-and-flat configuration is retained, with the entire seismogenic upper crust being above the “flat.” However, the existence of such low-angle aseismic horizons at depth is conjectural, and it is possible that the reverse faults continue into the lower crust as ductile shear zones, retaining their relatively steep dip. This is a significant issue, as the assumed geometry at depth influences palinspastic reconstructions and the estimates of shortening rates obtained from near-surface folds and faults (Yeats, 1993; Yeats *et al.*, 1997).

Other issues are concerned with why such steep reverse faults should be so common, and how they move at dips that are severely misoriented for frictional reactivation (Sibson and Xie, 1998). Where the reverse faults occur in sedimentary basins that were originally formed by extension, they may represent the reactivation of pre-existing normal faults in the basement (e.g., Jackson, 1980), which are expected to have similar dips (Fig. 4). Where sediment thickness variations across the faults can be seen on reflection profiles, as in the Late Cretaceous inversion province of the North Sea (e.g., Badley *et al.*, 1989), this reactivation mechanism can be verified, but it remains conjectural in areas that are still active.

Thus in the case of fold-and-thrust belts, seismology has focused attention on the fate of the basement, which had been rather neglected by earlier geological investigations that understandably concentrated on the commercially important sedimentary cover. Perhaps the most striking generalization is that any particular mountain belt shows a consistent tendency towards either high-angle reverse (e.g., Zagros, Tien Shan) or low-angle thrust (Himalaya, Greater Caucasus) dips in earthquakes. It is relatively rare to find both together in the same epicentral region. Possible examples of seismic activation of both a “ramp” and a “flat” in subevents of the same earthquake have been suggested (e.g., Nábělek, 1985; Stevens *et al.*, 1998), based on the interpretation of complex body waveforms.

4. The Importance of Earthquake Slip Vectors

Precise slip vector directions on faults are very difficult to determine on old, inactive structures, yet are relatively easy to

obtain from earthquakes. Several insights have arisen from the patterns of earthquake slip vector directions on faults over wide-deforming regions. The important conclusion to come out of the examples below is that, as far as big faults are concerned, it is the organization of the slip vectors in a deforming region that is the essential characteristic of the deformation, and the stresses simply adjust to produce slip in the right direction. Scholz (2000) reaches a similar conclusion for the San Andreas fault system in California.

4.1 Partitioning of Thrust and Strike-Slip Motion

The spatial separation, or “partitioning,” of strike-slip and thrust components of motion in obliquely converging belts onto parallel fault systems with orthogonal slip vectors was first noticed using earthquakes in island arcs (Fitch, 1972), but can also be seen on the continents. On a relatively local scale, where the strike-slip and thrust faults are only a few kilometers apart, such separation can be seen in fault plane solutions in California (Mount and Suppe, 1987; Ekström *et al.*, 1992), Irian Jaya (Abers and McCaffrey, 1988), Pakistan (Nakata *et al.*, 1990) and Iran (Berberian *et al.*, 1992, and Color Plate 10). It may also occur on a much larger scale, for example, in eastern Turkey and the Caucasus (Color Plate 10), where a deforming zone with a NW–SE strike accommodates roughly north–south convergence between Arabia and Eurasia (Jackson, 1992). Earthquakes in the southern part of this zone, in the Turkey–Iran border region, occur mostly on right-lateral strike-slip faults trending parallel to the zone, with slip vector directions west of the overall convergent motion (Color Plate 10). In the eastern half of the Greater Caucasus, the earthquakes occur mainly on thrusts, with slip vectors directed east of the overall motion, and roughly perpendicular to those on the strike-slip faults. In the intervening region of the Lesser Caucasus the deformation is more complicated (Jackson, 1992), but the spatial separation of the slip vectors and earthquake mechanisms over this broad region of $\sim 600 \times 600 \text{ km}^2$ is quite clear. GPS measurements confirm this separation (Color Plate 10), with velocities of sites in Armenia directed NE (reflecting the thrusting in the Greater Caucasus), and velocities only achieving the NNW direction relative to Eurasia at sites in southeast Turkey, within the strike-slip belt.

In kinematic terms, strain partitioning presents no difficulties, as it is simply one way of accommodating oblique shortening or extension. However, the dynamic reasons for it remain controversial (e.g., Molnar, 1992).

4.2 Rotations about a Vertical Axis

In the late 1970s it became apparent from paleomagnetic studies that large systematic rotations of crustal blocks about vertical axes were a common feature of distributed deformation on the continents (e.g., Beck, 1976; Luyendyk *et al.*,

1980). The way in which such rotations are achieved by faulting, and the relation between the fault geometry and the overall deforming velocity field are of great interest, because they potentially contain information about whether the deformation of the upper crust in such regions is controlled by the strength of the rigid fault-bounded blocks within it or by distributed flow in the aseismic lithosphere beneath (e.g., McKenzie and Jackson, 1983; England and Jackson, 1989). These issues are still controversial (e.g., Jackson, 1994; Molnar and Gipson, 1994; Bourne *et al.*, 1998) but, at least in some regions, we can now see how the faulting achieves the rotations, largely through observations of slip vectors.

For example, the earthquakes in Color Plate 10 show how NE–SW right-lateral strike-slip faulting in the northern Aegean Sea changes into a system of E–W normal faults in central Greece. The strike-slip faulting represents a continuation of the right-lateral shear on the North Anatolian fault system of Turkey, allowing the SW motion of the southern Aegean relative to Eurasia. The strike-slip motion in the northern Aegean must connect with the thrusting in the Hellenic Trench to the SW, or central Greece would be shortening, not extending (e.g., McKenzie, 1972). Thus the overall deformation in central Greece must involve a distributed NE–SW right-lateral shear, which can be seen in the velocity fields obtained from the seismicity (Jackson *et al.*, 1992) and, more accurately, from GPS measurements [(Color Plate 10); Clarke *et al.*, 1998; McClusky *et al.*, 2000]. In a conventional transform fault setting, the slip vectors on the strike-slip and normal faults would be in the same direction, but in Greece they are very different (Color Plate 10), with those on the active normal faults having azimuths in the range S to SSE rather than SW (Taymaz *et al.*, 1991). How can slip vectors to the south achieve an overall motion to the SW? The answer must be that the fault-bounded blocks rotate clockwise as they move, an inference that is supported by paleomagnetic measurements on Mio-Pliocene rocks in the region (Kissel and Laj, 1988). Various simplistic models attempt to illustrate the relation between the faulting and the velocity field (e.g., McKenzie and Jackson, 1983, 1986; Taymaz *et al.*, 1991), all of them suffering from limitations. The point to emphasize here is that it is the slip vectors on the normal faults, apparently in the wrong direction to achieve the overall motion, which indicate that rotations about vertical axes must occur.

Similar arguments have been made elsewhere. In eastern Iran and eastern Tibet the presence of E–W left-lateral faults in regions of probable N–S right-lateral shear strongly suggests that the fault-bounded blocks rotate clockwise (Jackson and McKenzie, 1984; England and Molnar, 1990). In the Western Transverse Ranges of California E–W thrust faults have slip vectors directed N to NE, in the wrong direction to accommodate the NW–SE right-lateral shear that dominates the regional velocity field (Jackson and Molnar, 1990; Molnar and Gipson, 1994). Once again, clockwise rotations, which in this case are well documented by

paleomagnetic declinations (Hornafius *et al.*, 1986), can reconcile the faulting with the velocity field.

4.3 Arc-Parallel Extension

The thrust fronts of both the Himalaya (Fig. 2) and the Hellenic arc of the Aegean are strongly curved. In both places slip vectors on low-angle thrusts are directed radially outward around the arc. Such motion requires an along-strike extension on normal faults on the concave side of the thrust front if the underthrusting block is rigid (Molnar and Lyon-Caen, 1989; Hatzfeld *et al.*, 1993). The along-strike extension of the Himalayan thrust front may also be related to strike-slip faulting in southern Tibet, if the entire concave side is analogous to the forearc region in an obliquely converging subduction zone (McCaffrey and Nábělek, 1998). In each case it is the slip vectors that reveal the relationship between the shortening and extension, which would otherwise be obscure. As McCaffrey and Nábělek (1998) point out, it is important to understand such geometric relationships and their consequences before speculating on the dynamic causes of the extension; in their interpretation the normal faulting in southern Tibet need not be related to its altitude, although the association of the style of strain with the topography is nonetheless striking.

5. Fault Scaling, Populations, and Growth

An important aspect of seismology is the ability to study earthquakes, and hence active faults, over a large range of scales. Two important generalizations stand out. First, the population distribution, or relative abundance of active fault sizes, represented by the Gutenberg–Richter frequency–magnitude (or frequency–moment) relation, is well known, and varies little regionally. Second, the ratio of coseismic displacement to length on a fault, which is a measure of the coseismic strain drop, also varies very little (typically between 10^{-4} and 10^{-5}) over a large range of earthquake sizes (e.g., Scholz, 1990). These two observations make it easy to sum the total seismic moment or strain released in a region, as the deficit caused by ignoring earthquakes smaller than a certain size can easily be calculated (e.g., Molnar, 1979; Scholz and Cowie, 1990).

An equivalent geological problem may be, for example, to calculate the total extension along a regional seismic reflection line across a basin, knowing that faults below the level of resolution cannot be detected (e.g., Marrett and Allmendinger, 1992). (This problem triggered an economically important and vigorous debate in the North Sea in the 1980s: see Ziegler 1983.) As in the case of earthquakes, the answer requires knowledge of both the population (relative size) distribution of the faults and a scaling law relating total fault displacement to fault size. But such observations are much harder to obtain

from geology because of the difficulty of sampling over size ranges of more than one or two orders of magnitude in the field (e.g., Dawers *et al.*, 1993). As a result, issues related to the scaling of cumulative slip on geological faults remain less certain and more controversial than those related to incremental slip in earthquakes (e.g., Marrett and Allmendinger, 1992; Cowie and Scholz, 1992a).

Nonetheless, this interest in the scaling of faults spawned a fruitful new area of research aimed at understanding how faults grow with time. Various models of fault growth have been produced (Watterson, 1986; Walsh and Watterson, 1988; Cowie and Scholz, 1992b,c) all of which are based on, or constrained by, an attempt to reconcile observations of slip in earthquakes with those of cumulative displacement on faults. As a result, structural geologists are now concerned not just with the pattern of active faults seen in the field, but with how it evolved to its present configuration (e.g., Wu and Bruhn, 1994; Jackson and Leeder, 1994; Jackson *et al.*, 1996; Keller *et al.*, 1998, 1999). It is hard to see how this subject could have developed without a knowledge of earthquake scaling laws.

6. Large-scale Continental Tectonics

Finally, seismology has contributed to the discovery of a number of important large-scale processes in continental tectonics. One of the earliest was the idea that continental material could be expelled sideways from a collision zone on strike-slip faults, thereby accommodating shortening while avoiding crustal thickening. This process was first noticed in Turkey (McKenzie, 1972), where the existence of single right-lateral (North Anatolian) and left-lateral (East Anatolian) fault systems bounding a rigid block (central Turkey) made it quite unambiguous and where it has subsequently been confirmed by GPS measurements (McClusky *et al.*, 2000). It also occurs to some extent in central Asia (e.g., Molnar and Tapponnier, 1975), but is more controversial there because the strike-slip faults occur in subparallel sets within areas that are deforming, allowing the alternative possibility that rotation about vertical axes is important (e.g., England and Molnar, 1990). Resolution of this doubt in Asia will eventually come from better knowledge of the overall velocity field, as in Greece (Color Plate 10). Such velocity fields are best obtained by GPS measurements, but it is worth noting that the first estimates of the deforming velocity fields in Asia, Greece, and Iran were obtained not by geodetic measurements, but from the spatial distribution of seismic strain rates obtained from earthquake catalogues (Holt *et al.*, 1991; Holt and Haines, 1993; Jackson *et al.*, 1992, 1995).

Another important process discovered using earthquakes is the extensional origin of many sedimentary basins on the

continents (McKenzie, 1978a). This idea, which now dominates the approach to the geological and hydrocarbon exploration of most passive continental margins and many intracontinental basins, came from noticing the association between active normal faulting, crustal thickness variations and heat flow in the Aegean Sea region (McKenzie, 1978b).

A final example, notable because of the obvious difficulty of proving this from the older geological record, is the localization of active faulting and high seismic strain rates near topographic gradients or, more precisely, near gradients in crustal thickness. This is noticeable in most deforming continental regions (e.g., Figs. 1 and 2), particularly in Iran and central Asia (e.g., Jackson and McKenzie, 1984; England and Houseman, 1986), and has important consequences for the dynamics as it suggests that buoyancy forces resulting from crustal thickness contrasts are an important driving force within the continents (e.g., England and McKenzie, 1982; England and Molnar, 1997).

7. The Future: Is Source Seismology Dead?

Earthquake seismology has contributed much to our understanding of structural processes, but now that other techniques have evolved that can also image slip on active faults on land, such as GPS (e.g., Hudnut *et al.*, 1996) and radar interferometry (e.g., Massonnet *et al.*, 1993), it is worth asking whether it has any more to offer, other than coverage of underwater areas. I believe it has, because seismology will always provide a faster and more easily accessible image of regional fault patterns than geodesy or radar, and because there is still a need to look at such patterns. Deforming velocity fields obtained with GPS are certainly more accurate and have better resolution than those obtained from seismicity, but on their own they offer an incomplete picture of what is happening. A complete description of the kinematics requires knowledge, not just of the overall velocity field, but also of how it is achieved by faulting (e.g., McKenzie and Jackson, 1983). Since the faulting can do this in a variety of ways, there is no alternative but to look, and seismology provides the best way of doing so. For example, the distributed shear that passes through central Greece (Color Plate 10) could be achieved by NE–SW strike-slip faults but is in fact achieved by normal faults that rotate clockwise. Knowing this leads to other questions, such as why the faulting has the orientation it does, what controls its sense and rate of rotation, and how the fault system evolves with time. Questions of this sort have dynamical implications, in particular concerning the relation between discontinuous deformation in the seismogenic upper crust and the (probably) more distributed flow in the aseismic lithosphere beneath (e.g., Jackson, 1994; Molnar and Gipson, 1994; Bourne *et al.*, 1998).

It is the ability of seismology to look at the pattern of active faulting over large regions that will remain its strength. The impressive organization of active faulting at a regional scale was noted at the start of this review. In addition, evidence is now mounting that when the fault patterns change they do so in an organized and rapid way. Once again, Greece provides an example (Color Plate 10). The northwestern Aegean and eastern seaboard of central Greece has a strong NW–SE structural fabric inherited from early Tertiary deformation. This region contains many large normal faults of this orientation that were active in the Quaternary and dominate the trend of the coastline. Yet, almost without exception, all the normal faulting earthquakes with well-constrained mechanisms show E–W striking nodal planes, cutting across this NW–SE trend [(Color Plate 10), Hatzfeld *et al.*, 1999]. This evidence, combined with geomorphological and structural evidence in the field, strongly suggests that activity moved from the NW–SE faults to the E–W faults within the Quaternary (e.g., Caputo and Pavlides, 1993; Leeder and Jackson, 1993; Hatzfeld *et al.*, 1999). What is remarkable is how quickly, and how completely, this change has occurred.

8. Conclusions

For many people, evidence from earthquake seismology has now become an unremarkable part of the structural geologist's armoury. The extent to which this has happened is best gauged by books such as *The Geology of Earthquakes* by Yeats *et al.*, (1997), and by the acceptability of questions that would not have been asked 20 years ago, such as: (1) is this structure large or small compared to the thickness of the seismogenic crust? (i.e., is it a big or a small fault?); (2) is this structure in the same orientation as when it was active, or has it been affected by rotations (about vertical or horizontal axes) or uplift?; (3) is there a modern analog of the structure or style of deformation being inferred?

This absorption of seismological insights into structural and tectonic geology is relatively new. Throughout the 1950s and early 1960s there were still arguments about whether all earthquakes occurred on faults, whether mountain building was still occurring today, and whether earthquakes and mountain building were connected at all. Most of this conceptual uncertainty was swept away by the advent of plate tectonics and by the demonstration by Burridge and Knopoff (1964) that slip on a fault generated a double-couple radiation field. But for a long time, perhaps uniquely among the traditional geological disciplines, structural geology was hampered by not being able to exploit the uniformitarian maxim that “the present is the key to the past,” because the present had nothing to offer. With the development of new seismological techniques and the accumulation of better earthquake data in the 1970s the situation finally changed and we could, for the first time, say “here's how faults are moving now: how does that help us interpret the

geological record?” Not surprisingly, many processes are much easier to see while they are active than after they have ceased. But there is no reason to believe that the processes we see active today were not also active in the past.

Acknowledgments

I would like to use this opportunity to apologize to all those readers whose work might have been quoted here, but isn't. In any review of this sort the selection of examples is somewhat arbitrary and, by concentrating on geographic areas with which I am most familiar and which I am most confident of discussing, I am aware there may be an appearance of bias. I can only assure those whose research in other regions might reasonably have been quoted also, that their omission arises from my timidity or ignorance, and not from any undervaluing of their work. I am grateful to Dan McKenzie for providing some historical perspective and to Philip England and Bob Yeats for reviews, though I alone am responsible for any misconceptions or errors. Cambridge Earth Sciences contribution 6012.

Rock Failure and Earthquakes

David A. Lockner and Nicholas M. Beeler

US Geological Survey, Menlo Park, USA

1. Introduction

This chapter summarizes experimental observations and related theoretical developments of faulted and intact rock properties related to earthquake nucleation, failure and dynamic slip. We will be concerned primarily with earthquakes occurring in the brittle crust. Intermediate and deep-focus earthquakes have unique mechanical considerations that are discussed in Section 7. We focus on repeatable laboratory observations and their direct implications for fault strength and stability. Important results that may be new, incomplete or controversial have also been included. To distinguish the well-established findings from others, the latter appear in “new and provisional results” sections.

Natural faults in the Earth’s crust are zones of localized shear that are inherently weaker than the surrounding intact rock (Chapter 29 by Sibson). Slip can occur slowly as aseismic creep or rapidly as earthquakes with long interevent times during which little or no slip occurs. Crustal faults have complex and irregular geometry, typically fractal in nature, that includes irregular, interlocked surfaces, offset segments, bends, and junctions. Since compressive stresses increase with depth due to the overburden, the natural tendency for irregular fault surfaces to move apart during sliding is suppressed. Instead, fault slip at depth involves grinding and crushing of grains and must involve continual fracture of asperities or interlocked regions. Breaking of asperities may in fact control the position and timing of earthquake nucleation. For this reason, we will examine the brittle fracture of intact rock as well as frictional properties of preexisting faults.

Experimental and theoretical rock mechanics studies have greatly influenced our understanding of earthquakes and related crustal processes. Many key theoretical advances have either originated or been tested and refined through observations of brittle deformation under controlled laboratory conditions. Although the association of earthquakes with crustal faults was established by the beginning of the 20th century (Lyell (1877) actually suggested a connection before this), important empirical relations for strength of rock and granular

material were developed much earlier. The Coulomb failure criterion for initially intact rocks was proposed in the late 18th century and continues to be of great practical use

$$|\tau| = c + \mu_i \sigma_n \quad (1)$$

where τ and σ_n are shear and normal stress resolved on the eventual fracture plane, c is cohesion, and μ_i is coefficient of internal friction. Here we define fracture as a loss of cohesion across a material plane, and failure as a loss of strength, thus fracture is a subset of failure. For the failure of intact material we conform to the standard definition that the coefficient of internal friction is the slope of the failure surface: $\mu_i = \partial\tau/\partial\sigma_n$ (Jaeger and Cook, 1971), the failure surface or envelope being the solution to the failure criterion, i.e., for Eq. (1) the failure surface is linear and μ_i is a constant. Griffith (1920) demonstrated the importance of flaws, which act as stress concentrators, in controlling the strength of brittle materials, materials whose ability to resist deformation decreases with increasing permanent deformation. Using this approach, fracture mechanics (e.g., Broek, 1982; Atkinson, 1987) has been highly successful in relating defect structures to fracture strength and related properties. Similar ideas have been a fundamental part of frictional contact theory where it is recognized that the real area of contact supporting stresses across a fault is a small fraction of the total fault area (Jaeger and Cook, 1971; Dieterich, 1978b; Dieterich and Kilgore, 1994).

Many of the theoretical advances in rock fracture and friction have their origins in metallurgy. Although the macroscopic phenomenology can be similar, the micromechanical deformation mechanisms are often distinct for metals and framework silicates. Brittle fracture in silicates commonly involves opening of cracks and an accompanying volume increase. Because this dilatational strain must do work against the ambient confining stress, Coulomb materials, unlike metals, are characterized by a pressure sensitivity of yield strength as expressed in Eq. (1).

The basic concept of friction or frictional resistance of two surfaces in contact, the ratio of the shear resistance to the

surface normal stress, is referred to as Amontons' law and was developed about eighty years before the Coulomb criterion (Rabinowicz, 1965; Jaeger, 1969). In this case, shear resistance (f_s) is related to the normal force (f_n) acting on the surface by $|f_s| = \mu_f f_n$, where μ_f is coefficient of friction. Dividing by the area of the surface gives

$$|\tau| = \mu_f \sigma_n \quad (2a)$$

For many materials, spanning a wide range of mean stress, μ_f is only weakly dependent on normal stress. Friction will depend both on the material filling the interface (fault gouge) and on the surface geometry (surface roughness, coherence or degree of interlocking of surfaces). For example, joint systems, which are formed by tensile opening of fractures with little net shearing, can result in clean, well-mated surfaces that have higher shear strength than surfaces with uncorrelated roughness. For coherent surfaces, shear strength may not vanish at zero normal stress and a more accurate empirical description of shear strength becomes

$$|\tau| = S_0 + \mu_f \sigma_n \quad (2b)$$

where S_0 is an 'inherent' shear strength similar to cohesion in Eq. (1) (Jaeger and Cook, 1971). The quantity most easily measured and most often used in studies of rock friction is the simple ratio of shear to normal stress. We will refer to this ratio

as friction or frictional resistance, denoted by μ , to distinguish it from the coefficient of friction μ_f , so that Eq. (2b) gives

$$\mu = \frac{|\tau|}{\sigma_n} = \frac{S_0}{\sigma_n} + \mu_f \quad (3)$$

High temperature, high pressure or the addition of reactive pore fluids may allow for activation of ductile deformation mechanisms (mechanisms whereby permanent deformation can be accommodated without loss of strength) such as dislocation glide or pressure solution, and can allow deformation that lacks the pressure sensitivity characteristic of friction and fracture. Thus, both μ_i and μ_f are expected to decrease with increasing depth in the crust (Mogi, 1966), and in fact laboratory measurements indicate that μ_i , μ_f and μ decrease with increasing mean stress $(\sigma_1 + \sigma_3)/2$ or normal stress (Fig. 1b). Normal stress increases with depth and provides a convenient independent variable for identifying trends in shear strength and other fault-related properties. However, when considering failure of intact rock, there is no preexisting fault plane and normal stress becomes a less useful concept. In this case, mean stress provides a good alternative and will be used throughout this chapter.

Although it is tempting, based on observations such as shown in Figure 1a, to treat friction as a material property, this assumption may not be correct. Some effects resulting from surface geometry can be accounted for by adjusting S_0 .

FIGURE 1 (a) Shear-normal stress plot for Westerly granite showing peak intact strength and frictional strength. (b) Alternative measures of strength for intact and faulted Westerly granite.

However, other geometric properties related to the deformation of granular material between rigid fault blocks also affect shear strength. In an idealized sense, a fault zone can be described mechanically as a thin, weak layer sheared between rigid blocks. The boundary conditions for this geometry require that normal strains in the gouge layer in the plane of the fault must be zero and average flow lines must eventually become parallel to the fault walls, imposing constraints on the stress field that develops within the gouge layer (Spencer, 1982; de Josselin de Jong, 1988; Rice, 1992; Savage *et al.*, 1996; Savage and Lockner, 1997). The strains resulting from average simple shear deformation imposed on a gouge layer by the fault walls are inconsistent with strains resulting from flow of a Coulomb material (Byerlee and Savage, 1992). As a result, complex structures such as Riedel shear bands develop in the fault gouge (Gu and Wong, 1994; Savage *et al.*, 1996) which reflect a heterogeneous stress field that develops within fault zones in response to deformation (Mandl *et al.*, 1977; Morgan and Boettcher, 1999).

Laboratory measurements show that numerous parameters in addition to normal stress or confining pressure affect strength of both fault surfaces and intact rock. These include mineralogy, porosity, cementation, packing geometry of gouge, surface roughness, coherence of surfaces, angularity and size of gouge particles, temperature, pore fluid pressure and composition, deformation rate, deformation and stress history, fabric, foliation, or other anisotropic properties. Sample size is reported to affect intact strength, but appears to have little or no effect on frictional strength. Some of these effects are discussed individually in subsequent sections. Pore fluid pressure, in particular, has a first order effect on rock and fault strength in cases where there is well-connected porosity. This effect is discussed in more detail in Sections 2.3.2 and 5. For now, we note that “effective” normal stress should be substituted into Eqs. (1), (2), and (3) where an effective normal stress component is the normal stress reduced by pore pressure: i.e., $\sigma_{n,\text{eff}} = \sigma_n - p$ (Terzaghi, 1929; Hubbert and Rubey, 1959).

2. Brittle Fracture

For theoretical development or numerical modeling, it is common to assume that earthquakes occur in preexisting fault zones. For a number of reasons, however, we will include analysis of the rupture process in both intact and prefractured rock (cf. Section 4.2). Although the Earth’s crust is generally permeated with preexisting fractures and joints, it is not known what fraction of earthquakes occur on preexisting faults, what percentage of any single earthquake rupture surface represents new faulting (especially for earthquakes that jump fault segments), or whether rupture nucleation might occur at jogs or locked segments and involve breaking of rock which is at or near the intact rock strength. Also, there are many similarities

between the mathematical analysis of intact rock deformation and deformation on faults. The micromechanical mechanisms for fracture and sliding on faults both involve grain breakage, grain rotation, crack propagation, and in many cases plastic deformation mechanisms. Fault zone materials will be altered by passage of pore fluids, but this process also occurs in intact rock. Finally, in the long periods between earthquakes, faults can be expected to heal and restrengthen by an amount which, in the limit, would return to intact rock strength. For these reasons, a proper review of rock friction should also include discussion of rock fracture.

A number of comprehensive studies and reviews of rock failure, faulting and rheology currently exist (Handin, 1966; Jaeger and Cook, 1971; Bock, 1978; Lama and Vutukuri, 1978; Paterson, 1978; Lambe and Whitman, 1979; Kirby and McCormick, 1984; Kirby and Kronenberg, 1987; Mandl, 1988; Scholz, 1990; Evans and Dresen, 1991; Lockner, 1995). Readers are encouraged to refer to these studies for additional information. Many of the effects discussed in this section have direct bearing on how rocks deform along preexisting faults and provide a useful framework for much of the discussion of earthquake processes.

2.1 Basic Relations

The relations between fault orientation angle β , fault normal angle ψ ($= (\pi/2) - \beta$), and stress components, including maximum compressive (σ_1) and minimum compressive (σ_3) principal stresses (Fig. 2), follow directly from expressing the state of stress on planes which contain the intermediate principal stress axis as a function of the extreme principal stresses

$$\tau = \frac{1}{2}(\sigma_1 - \sigma_3) \sin 2\beta \quad (4a)$$

$$\sigma_n = \frac{1}{2}[(\sigma_1 + \sigma_3) - (\sigma_1 - \sigma_3) \cos 2\beta] \quad (4b)$$

Here and throughout we take compressive stresses and contractive strains as positive. As indicated by Eq. (4), the orientation of the failure plane is assumed to contain and be independent of the intermediate principal stress.

Laboratory failure tests conducted at different conditions can be used to construct the failure envelope, defined as the locus of points in shear versus normal stress space which define failure (the Mohr plane) (Fig. 2). The simplest laboratory test geometries are uniaxial compression ($\sigma_1 = \sigma_c$, $\sigma_2 = \sigma_3 = 0$) leading to failure stress state “U” in Fig. 2, and uniaxial tension ($\sigma_1 = \sigma_2 = 0$, $\sigma_3 = \sigma_t$) shown as stress state “T”. Tensile failure occurs on a fracture oriented perpendicular to the maximum tensile stress direction ($\beta = 90^\circ$), whereas compressive failure involves shearing on a fault inclined at smaller β (typically in the range $20^\circ < \beta < 45^\circ$). More complicated testing conditions are appropriate for deformation tests relevant to earthquake failure, which require higher normal stress and independent variation of one or more

FIGURE 2 (a) Relation between principal stresses at failure. (b) Mohr failure envelope showing relation between stresses and failure parameters. $\beta = (\pi/2) - \psi$ is the angle between failure surface and direction of maximum principal stress σ_1 .

stress components. The two most common test geometries are shear box or direct shear and triaxial. Direct shear machines allow for independent variation of shear and normal stress on the sliding surface. Triaxial machines are the most common method of testing samples at confining pressures as high as 1 GPa, controlled pore fluid pressure, and temperatures relevant to the crust and upper mantle. A restriction on standard triaxial tests is that a fluid is used to apply confining pressure P_{conf} so that $\sigma_2 = \sigma_3 = P_{\text{conf}}$. Rotary shear machines, where confining pressure, normal stress, shear stress (torque), and pore pressure can be varied independently, are also particularly useful in friction studies since significantly larger displacements can be achieved in this geometry than in any linear displacement apparatus. However, the direct shear and unconfined rotary shear geometries lead to difficulties in controlling pore pressure and temperature.

The steep slope for the failure envelope in Figure 2a shows the strong pressure sensitivity of failure strength for dilatant materials. A Mohr representation in which shear stress is plotted versus normal stress, is shown in Figure 2b (Jaeger and Cook, 1971). For application to the Earth, it is often assumed and observed that failure occurs when Eq. (1) is first satisfied on the most favorably oriented plane. This assumption leads to additional constraints on the stress state

and fault orientation,

$$\phi_i = \tan^{-1} \mu_i = \frac{\pi}{2} - 2\beta \quad (5a)$$

$$\tan 2\beta = \frac{1}{\mu_i} \quad (5b)$$

$$\sigma_1 = \sigma_c + [(\mu_i^2 + 1)^{1/2} + \mu_i]^2 \sigma_3 \quad (5c)$$

Equations (5) are Mohr–Navier–Coulomb relations.

2.2 Conceptual Fracture Model

As mean stress increases with depth in the shallow to mid crust due to the increase in overburden, both frictional and intact rock strength can be expected to increase. If special conditions result in near-lithostatic fluid pressure, that is, pore pressure equivalent to overburden (i.e., magma intrusion or trapped pore fluid), then the minimum effective principal stress can be low or negative and the rock can fracture in tension. In the case of earthquakes, however, focal mechanisms indicate shear rather than tensile failure. Rocks are generally about ten times stronger in compression than in tension (Lockner, 1995), reflecting the difficulty of propagating a large-scale shear

fracture (generally involving dilatancy) through a compressively loaded brittle material. It is well known that the failure process in rock involves microcrack growth. Open pores, contrasts in elastic properties of adjacent minerals, and weak grain boundaries can all act as stress concentrators in compression (Peng and Johnson, 1972; Tapponnier and Brace, 1976) and shearing along surfaces oblique to the maximum compressive principal stress σ_1 is likely to play an important role in the development of large local stresses (Peng and Johnson, 1972; Horii and Nemat-Nasser, 1986; Sammis and Ashby, 1986; Ashby and Sammis, 1990; Lockner *et al.*, 1992b). The local stresses induced near the crack tips contain a component of tension which leads to local tensile failure before the fracture toughness for failure in shear is achieved (Lawn and Wilshaw, 1975). As a result, tensile “wing” cracks grow aligned subparallel to the σ_1 direction. Unlike the case of remotely applied tensile stress, two important stabilizing processes take place during the loading of cracks in compression. First, as wing cracks extend, stress intensity decreases, and additional deviatoric stress must be applied to cause further crack growth (Costin, 1983, 1987; Horii and Nemat-Nasser, 1986). Second, diagonal flaws, which are favorably oriented to act as nucleation points for shear failure, propagate out-of-plane (parallel to σ_1) and cannot maintain the necessary shear geometry (Lawn and Wilshaw, 1975). Eventually, crack densities become sufficiently large for significant crack interaction to occur, leading to the nucleation of a proto-fault: a shear fracture connecting en-echelon arrays of the dilatant microcracks (Peng and Johnson, 1972; Horii and Nemat-Nasser, 1986; Sammis and Ashby, 1986; Costin, 1987; Kemeny and Cook, 1987; Ashby and Sammis, 1990; Du and Aydin, 1991; Lockner *et al.*, 1992b; Reches and Lockner, 1994). Finally, quasi-static fault growth experiments (Lockner *et al.*, 1991, 1992a) have demonstrated that following nucleation, the shear fault propagates inplane due to its own stress field (Fig. 3). Although the fracture propagates as mixed shear modes II and III, the fracture tip is surrounded by a process zone, much like the earthquake rupture zone described by Rice (1980). In this high-stress region, energy is dissipated by the growth of a halo of microcracks (primarily tensile (Moore and Lockner, 1995)) as the fracture advances through the rock. Similar results have been observed for damage zones surrounding natural faults (Vermilye and Scholz, 1998). The acoustic emission experiments provide an important constraint on nucleation. In past studies it was often argued that the eventual fault plane began forming, as a region of high microcrack damage, well before peak strength. Although this interpretation may hold for samples containing large preexisting flaws, it appears that in homogeneous, isotropic rocks, the location of the eventual fault plane is not correlated in any obvious way to precursory, localized damage. Similar results have been reported in field studies (Linde and Johnston, 1989; Johnston and Linde, 2002) where nucleation zones for moderate-sized earthquakes were inferred to be less than 0.1% of the coseismic rupture surface area.

FIGURE 3 Acoustic emission (AE) hypocentral locations during fault formation of initially intact Westerly granite. Time progresses from left to right. Middle: Figures view sample along strike of eventual fault plane which appears as diagonal feature in (e) and (f). Top: Same AE events viewed perpendicular to strike. Bottom: Accompanying stress–displacement curve indicates segments of the experiment from which acoustic emission plots are made. Fault nucleation occurs in (d).

2.3 Factors Affecting Fracture Strength of Rock

2.3.1 Confining Pressure Effect

Confining pressure affects brittle fracture strength by suppressing the growth of dilatant microcracks. Microcracks tend to grow parallel to σ_1 when a sample is loaded in compression by locally overcoming the ambient compressive stress field near crack tips and developing a localized region of tensile stress. This process requires some specialized mechanism such as slip along grain boundaries or bending of a rigid grain that is adjacent to an open pore or more compliant grain (Peng and Johnson, 1972; Tapponnier and Brace, 1976; Sammis and Ashby, 1986; Reches and Lockner, 1994). Such mechanisms are generally enhanced by deviatoric stress and suppressed by mean stress. In addition, slip along grain boundaries will

not occur until frictional contact strength, which increases with mean stress, is overcome. The overall strengthening effect can be represented in a shear stress–normal stress plot (Mohr–Coulomb failure envelope) such as Figure 1a for Westerly granite. In general, the failure envelope is concave towards the normal stress axis so that a linear failure criterion such as Eq. (1) may not be a satisfactory approximation. This curvature becomes most important when experimental data span a broad range of normal stress. Some minerals, such as calcite, undergo a brittle–ductile transition within this pressure range and exhibit severe curvature of the failure envelope. Furthermore, the difference between intact failure strength and frictional sliding strength vanishes at high pressure (Byerlee, 1967; Ismail and Murrell, 1990). A good empirical fit to the intact rock strength in Figure 1 (Lockner, 1998) is provided by

$$\sigma_1 = \sigma_3 + (46\,660 + 5128.7\sigma_3)^{1/2} - 8.3 \text{ MPa} \quad (6)$$

where stresses are in MPa.

The majority of strength measurements have been conducted under uniaxial or “triaxial” stress conditions in which $\sigma_2 = \sigma_3$. A limited number of true triaxial measurements have been performed to explore the effect of intermediate principal stress on failure mode. While the most commonly used failure criteria (e.g., Mohr–Coulomb) assume that failure is independent of intermediate stress, experimental evidence demonstrates that this assumption is not strictly true (Mogi, 1967, 1970; Amadei *et al.*, 1987).

2.3.2 Pore Fluid Pressure and Effective Pressure Law

Pore fluids can affect fracture strength through a direct pressure effect as well as through chemical interactions with the rock matrix. Mechanically, pore pressure acts to reduce the normal stress tensor components throughout the rock mass according to the effective pressure law (Hubbert and Rubey, 1959)

$$\sigma_{n,\text{eff}} = \sigma_n - \alpha p \quad (7)$$

where α is a constant related to pore geometry. Although variations in α have been measured for the effect of pore pressure on transport properties (Walsh, 1981), $\alpha = 1$ is appropriate for fracture strength of rock with well-connected porosity. If fluid pressures in the crust were low, the increase in mean stress and temperature with depth, due to overburden pressure, should result in large shear strength and the gradual change from brittle to ductile deformation in the mid to lower crust (as suggested by the convergence of frictional and intact strength in Fig. 1). The normal hydraulic head for well-connected porous material will offset the overburden pressure by approximately one-third. However, for isolated porosity at depth, normal consolidation and dewatering processes can compress pore fluids to well above hydrostatic pressures and under proper circumstances may lead to repeated episodes in which the rock is hydraulically

fractured. There is currently considerable interest in fluid overpressure phenomena and their relation to oil reservoir partitions (Hunt, 1990; Powley, 1990) as well as to larger-scale crustal processes such as earthquake cycles and the reduction of strength of mature faults (Byerlee, 1990, 1992, 1993; Nur and Walder, 1990; Rice, 1992; Miller *et al.*, 1996; Sibson, 2002) (see Section 3.2).

Since water reacts with silicates to disrupt the Si–O bond, pore fluids can have a profound chemical effect on the physical properties of crustal silicate rocks. CO_2 concentration plays a similar role in the diagenesis and metamorphism of carbonates. Crack healing, cementation, and densification all act to strengthen rock with time (Hickman and Evans, 1992). By contrast, chemically assisted crack growth is the primary mechanism for stress corrosion and static fatigue (subcritical crack growth) at temperatures in the 0–200°C range (Rutter and Mainprice, 1978; Kranz, 1980; Kranz *et al.*, 1982; Lockner, 1993b). Subcritical crack growth is crack extension at crack tip stress below the critical stress intensity K_{IC} needed to split lattice bonds ($K_I < K_{IC}$) (Atkinson and Meredith, 1987; Costin, 1987). Subcritical crack growth rate v is generally related to K_I through a power law

$$v = A_1 K_I^n \quad (8)$$

or exponential form

$$v = A_2 \exp(b_2 K_I) \quad (9)$$

where A , b , and n are empirical constants. An alternative view relates crack growth rate to energy release rate G_I ($\propto K_I^2$) (Lockner, 1993b):

$$v = A_3 \exp(b_3 G_I) \quad (10)$$

Experimental data are insufficient to identify which form fits best. However, there are theoretical arguments, based on reaction rate theory, to prefer Eq. (9) or (10) (Costin, 1983; Lockner, 1993b). Nominal values for n at room temperature and in wet rock (Atkinson, 1987, Table 11.6) are: 15–40 for quartz and quartz rocks; 10–30 for calcite rocks; 30–70 for granitic rocks; and 25–50 for gabbro and basalt. A typical value for b_2 for room temperature granite is $0.04 \text{ (MPa m}^{-1/2})^{-1}$. The corrosive effect of the pore fluid can be altered significantly by varying the activity of dissolved species as well as altering the electrochemical potential (Dunning *et al.*, 1980; Ishido and Mizutani, 1980; Atkinson and Meredith, 1987; Evans and Dresen, 1991; Hickman and Evans, 1991).

2.3.3 Strain Rate

In the brittle deformation field, rocks typically exhibit a pseudo-viscous effect prior to failure which is reflected in a strength increase with increasing strain rate. This effect is best known in the mining industry as static fatigue in which a pillar or other load-bearing structure will fail after some period of time under

constant load. Subcritical tensile crack growth has been identified as the principal mechanism responsible for static fatigue in rock (Kranz, 1980; Kranz *et al.*, 1982; Lockner, 1993b) and has been studied in recent years (Atkinson and Meredith, 1987). The strain-rate dependence of rock strength has been measured in the laboratory at rates above $10^{-10} \text{ sec}^{-1}$ which is generally much faster than geologic rates even in tectonically active regions. However, the lower limit does represent a useful limit for many engineering applications. Experimental results covering a broad range of strain rates are shown in Figure 4. Average strain rates have been obtained from static fatigue tests on Barre granite (Kranz, 1980) by dividing time-to-failure data by total inelastic strain. Various studies (Costin, 1983; Lockner, 1993b) have been successful in relating this macroscopic relation between stress and strain rate to subcritical microcrack growth rate and its sensitivity to stress intensity at crack tips. They determined an apparent activation volume of $0.43 \pm 0.04 \text{ kJ MPa mol}^{-1}$ ($4.3 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$) for crack growth in granite creep experiments. This approach provides a link between energetics of microcrack extension and bulk pseudoviscous response of rocks in creep (Lockner, 1998). It may also prove useful as a way to incorporate time-dependent effects in damage mechanics applications (Costin, 1987). This rate sensitivity is often expressed as a power law dependence of the form

$$\sigma_{\max} = a\dot{\epsilon}^n \quad (11)$$

Typical rate sensitivities in this regime are $0.02 \leq n \leq 0.04$.

FIGURE 4 Effect of strain rate on brittle fracture strength. Trend lines in lower-right quadrant are from dynamic tensile fracture experiments (Goldsmith *et al.*, 1976.)

By using shock and other impulsive loading techniques, strain rates in excess of 10^4 sec^{-1} have been achieved for samples failing in tension (Grady and Lipkin, 1980). Although some question remains as to the dependence of the measurement on machine effects and boundary conditions, numerous experiments show a transitional strain rate of approximately 10 sec^{-1} above which significantly larger rate dependence is observed. High-rate tensile experiments, taken from Grady and Lipkin (1980), are summarized in the lower-right quadrant of Figure 4 as trend lines without accompanying data values. An upper limit of $n \leq 1/3$ is indicated by both theory and experiment (Brace and Jones, 1971; Green *et al.*, 1972; Lipkin and Jones, 1979; Grady and Lipkin, 1980; Olsson, 1991) for rate sensitivity under these conditions.

2.3.4 Temperature

Mechanisms of crystal plasticity involving dislocation motion, diffusion of point defects, and twinning are thermally activated and will dominate brittle cracking as temperature increases (Kirby and Kronenberg, 1987; Evans and Dresen, 1991). Some minerals, such as halite and calcite, will deform ductilely at room temperature if sufficient confining pressure is present to suppress brittle crack growth (Fredrich *et al.*, 1989). However, dry quartz appears to deform brittlely at room temperature even at confining pressures in excess of 1 GPa (Tullis and Yund, 1977). As previously mentioned, water has a significant effect on pressure-assisted grain-boundary deformation mechanisms such as pressure solution (Blanpied *et al.*, 1991; Hickman and Evans, 1991). These fluid-assisted mechanisms will often dominate at intermediate temperatures and, over geologic time scales, may play an important role in determining rock strength at room temperature (Rutter and Mainprice, 1978). Thus, even in the brittle regime, increasing temperature tends to reduce fracture strength (Bragg and Andersland, 1981; Sayles and Carbee, 1981; Wong, 1982a). The effect of temperature on fracture strength of Westerly granite is shown in Figure 5.

2.3.5 Sample Size and Scaling

Laboratory studies in which pressure, temperature and other environmental conditions are controlled have provided strength data relevant to natural faulting and seismicity. However, the scaling of these data to field applications remains problematic (Pinto da Cunha, 1990). For example, the largest laboratory fault models (approximately 1-m^2 surface) are many orders of magnitude less than the fault area involved in a moderate earthquake. A general result of fracture mechanics analysis is that stress intensity at the tip of a flaw scales as the square root of the flaw size. Consequently, larger samples, which can contain larger flaws, are more likely to be weak. This argument assumes, of course, that small samples with visible flaws (and certainly flaws that completely bisect the sample) will be rejected and not included in the strength statistics. However, the degree of weakening has not been well determined and should

FIGURE 5 Effect of temperature on brittle fracture strength of nominally dry Westerly granite.

FIGURE 6 Effect of sample size on fracture strength. Observed weakening is up to 70% per decade increase in sample length. All data are for uniaxial experiments.

vary from rock to rock depending on the flaw-size distribution. Scaling procedures have been proposed (All  gre *et al.*, 1982; Madden, 1983) that address this problem. In addition, both laboratory and field studies have been conducted (Mogi, 1962; Koifman, 1963; Bieniawski, 1968; Hodgson and Cook, 1970; Pratt *et al.*, 1972; Singh and Huck, 1972; Herget and Unrug, 1976; Heuze, 1980; Dey and Halleck, 1981) that show a general weakening with increased sample size (Fig. 6). This effect can be large: as much as a 70% strength loss per decade sample size for the weathered diorite studied by Pratt *et al.* (1972). Available data are insufficient to allow a clear understanding of this effect. It is intriguing that the weaker rock types show the

greatest size effect. Pratt *et al.* (1972) noted a decrease in size sensitivity for samples greater than 1-m length for both diorite and coal and suggested that this may represent an upper limit to the weakening region. Due to the small amount of existing data, it is not yet clear to what extent these tendencies can be generalized. If flaw size is the correct explanation for the weakening effect, then sample strength will depend as much on crack-size distribution as on mineralogy. Furthermore, the studies cited here are all unconfined. As discussed in Section 3, we may expect large rock masses, especially in tectonically active regions, to support stresses that are comparable to their frictional strength rather than laboratory-measured intact strength (Townend and Zoback, 2000).

3. Friction and Crustal Faults

Numerous theoretical arguments have been proposed to explain frictional properties of rocks; many of which have met with reasonable success in matching experimental observations. Yet, natural faults are complex systems, and many complicated and competing processes probably occur during deformation of fault zones. At present, fault rheologic models should be considered empirical. As more sophisticated and precise experimental observations are made, the corresponding mathematical descriptions have invariably become more complicated. There are many earthquake-related applications that can take advantage of linearized approximations of frictional properties where the non-linear aspects of time-dependent failure or fluid-rock interactions are of less importance.

3.1 Byerlee's Law and Incipient Failure

It has already been noted that Eq. (3) provides a lowest order approximation of rock friction, especially in the lower temperature brittle deformation field. Byerlee (1978) compiled laboratory friction data for rocks and minerals and found that many silicates and carbonates had very similar frictional strengths. He suggested that the characteristic concave-downward trend of shear strength versus normal stress could be adequately approximated by a piecewise linear function often referred to as Byerlee's law:

$$\begin{aligned} \tau &= 0.85\sigma_n & \sigma_n < 200 \text{ MPa} \\ \tau &= 50 \text{ MPa} + 0.6\sigma_n & 200 < \sigma_n < 1700 \text{ MPa} \end{aligned} \quad (12)$$

As discussed in the next section, Eq. (12) has proved to be a popular approximation for shallow to mid crustal strength where details of mineralogy or stress state may not be known. It should be noted that many hydrated minerals and especially sheet silicates with good basal cleavage or which accommodate interlayer water have frictional strength significantly lower than that described by Eq. (12) (see Section 3.2). Frictional

resistance μ as determined by Eq. (12) is plotted in Figures 1a and b. This function, or values of frictional shear strength given by Eq. (12) will be used as a convenient reference in this paper.

Let us assume for the moment that the strength of the brittle crust can be adequately represented by granodiorite. Although this is an obvious simplification of the range of lithologies that may be found in the continental crust, it should provide a reasonable approximation of both intact and frictional strength for many low-porosity, unaltered crystalline rocks. The intact strength curve shown in Figure 1a, which is derived from granitic samples chosen to be free of macroscopic flaws, provides a reasonable approximation to the upper strength limit of the crust for rock volumes free of faults or joints. For fractured rock masses, containing faults or joints of all orientations, the most favorably oriented faults will fail when the stress state intersects the frictional strength curve (Eq. 12). In this case, the frictional strength would provide a practical upper limit to crustal strength in the brittle field. The limit of differential stress $\sigma_d = \sigma_1 - \sigma_3$ in the crust predicted by Eqs. (2b) and (5b) can be written

$$\sigma_d = \frac{2(S_0 + \mu_f \sigma_{n,eff})}{\cos(\tan^{-1} \mu_f)} = \frac{2(S_0 + \mu_f \sigma_{n,eff})}{\cos \phi_f} \quad (13)$$

where the friction angle $\phi_f = \tan^{-1} \mu_f$ and $\tan 2\beta = 1/\mu_f$. Equation (13) specifies the differential failure stress for frictional failure, and by substituting c for S_0 and μ_i for μ_f , Eq. (13) can predict differential failure stress for rock fracture. Although intact rock strength is an appropriate stress limit at the surface of the Earth and in some near-surface applications such as mining, in the case of earthquake faulting, Eq. (13) appears to serve as an upper limit for stress in the upper crust, especially in intraplate regions. This frictional strength limit is confirmed by *in situ* measurements made at depths up to 9 km (Hickman, 1991; Townend and Zoback, 2000) (also see Chapter 40 by McGarr *et al.* and Chapter 34 by Zoback and Zoback). These field observations indicate that σ_d generally does not exceed laboratory measurements of the differential strength of faulted, dry, anhydrous silicates (i.e., Byerlee's law).

Using the same assumptions used to derive Eq. (13), the variation of stress with depth in the brittle part of the crust can be estimated from Eqs. (2b) or (12) provided the magnitude of one of the principal stresses is known. The magnitude of one of the principal stresses can be deduced in normal and thrust faulting environments by using Anderson's assumption that near the Earth's surface one of the principal stresses is vertical due to the lack of shear stress on Earth's free surface (Anderson, 1951), and the vertical stress is given with depth by the overburden. This assumption leads to expressions for normal stress on critically oriented faults in reverse fault

environments where $\sigma_v = \sigma_3$:

$$\sigma_n = \frac{\sigma_3 - (S_0 - \mu_f p) \left(\mu_f - \frac{1}{\cos \phi_f} \right)}{1 + \mu_f^2 - \frac{\mu_f}{\cos \phi_f}} \quad (14a)$$

and for principally oriented normal faults where $\sigma_v = \sigma_1$:

$$\sigma_n = \frac{\sigma_1 - (S_0 - \mu_f p) \left(\mu_f + \frac{1}{\cos \phi_f} \right)}{1 + \mu_f^2 + \frac{\mu_f}{\cos \phi_f}} \quad (14b)$$

(Fig. 7) (as follows from Sibson (1991)). (Here we have used the definition $\phi_f = \tan^{-1} \mu_f$.) Equations (14a) and (14b) as depicted in Figure 7 indicate the Anderson–Byerlee predictions for depth varying stress in the shallow crust.

3.2 Strength of Crustal Faults

Laboratory measurements of frictional strength indicate that many common silicates should have sliding strengths proportional to effective normal stress as represented by Byerlee's law ($0.6 \leq \mu \leq 0.85$). In fact, field observations of crustal stress,

FIGURE 7 Anderson–Byerlee differential stress with depth in reverse (Rev) and normal (Nor) faulting environments, with hydrostatic (Hyd) fluid pressure of 10 MPa km^{-1} and no fluid pressure (Dry).

obtained primarily from shallow borehole stress measurements (see, for example, Zoback *et al.*, 1987; Townsend and Zoback, 2000, and other chapters in this volume), show many crustal faults in a stress state consistent with a slightly wider range of friction of $\mu \sim 0.5$ –1.0. The occurrence of faults with strengths somewhat below Byerlee's law can be explained by the presence of weak mineral phases (especially at shallower depths). Fault zones are generally wet and contain ground-up and altered gouge with significant hydrated mineral phases. In particular, many clays, micas and other hydrous phases which are common products of chemical reactions between water and anhydrous silicates have lower frictional strength than Byerlee's law (Raleigh and Paterson, 1965; Byerlee, 1978; Wang *et al.*, 1980; Moore *et al.*, 1983, 1986, 1996, 1997; Kronenberg *et al.*, 1990; Morrow *et al.*, 1992, 2000) (Fig. 8). Conversely, faults that are stronger than Byerlee's law may be either partially healed by precipitation reactions, or due to complex fault geometry, require breaking of intact rock to accommodate slip.

Although the strength of many faults seems to conform to Eq. (12), a long-standing debate concerns the strength of major plate-bounding faults and the San Andreas fault (SAF) in particular (see, for example, Hickman, 1991; Scholz, 2000). In what has come to be known as the heat flow paradox, field measurements have failed to detect any significant heat flow

anomaly associated with the SAF (Brune *et al.*, 1969; Lachenbruch and Sass, 1980). Whether an active fault dissipates energy either through creep or dynamically during earthquakes, only a small portion of the consumed energy is expended in creating new fractures and surface energy (Wong, 1982b). Similarly, at least for strong faults, seismic energy radiated by earthquakes is also a relatively small fraction of the total energy expended (Lockner and Okubo, 1983; McGarr, 1998). The majority of energy associated with crustal fault deformation should be dissipated as shear heating and, for a fault such as the San Andreas that has been active for millions of years, should produce a measurable heat flow anomaly at the Earth's surface (Brune *et al.*, 1969; Lachenbruch and Sass, 1980). The lack of such an anomaly has been interpreted to imply an average shear strength of the top 14 km of the SAF of less than 20 MPa (or $\mu < 0.2$). Recent stress orientation measurements made at depths of 1–4 km adjacent to the San Andreas (Mount and Suppe, 1987; Zoback *et al.*, 1987; Shamir and Zoback, 1989) indicate that the greatest principal stress is at an angle approaching 90° to the fault which requires the fault to be weak relative to surrounding subsidiary faults that are oriented more favorably relative to the ambient stress field and yet remain locked while the San Andreas accommodates slip. Stress orientations determined along the SAF imply either an average coefficient of friction less than 0.1 or superhydrostatic fluid pressure (Lachenbruch and McGarr, 1990). Recently Scholz (2000) has proposed a model for a strong SAF in which plate-driving forces are applied as horizontal tractions at the base of the crust. This model also predicts rotation of principal horizontal stresses near the SAF and suggests that the inference that large plate-bounding faults such as the San Andreas are anomalously weak, remains open to debate.

If the SAF is in fact weak relative to its surroundings, then a number of possible explanations have been proposed for the apparent discrepancy between field and laboratory strength observations: (1) dynamic rupture effects reduce normal stress across the fault during large earthquakes so that dynamic sliding strength is low; (2) high fluid pressure reduces effective normal stress and therefore shear strength; and (3) intrinsically weak minerals are responsible for low shear strength on mature faults. In terms of field observations of low heat flow, it may be possible that ground-water circulation acts to broaden and suppress a heat flow signature resulting from heating at depth. However, the borehole stress orientations are not subject to this effect and must be explained in some other manner (i.e., Scholz, 2000).

The possibility of low effective normal stress acting across the fault during large earthquakes has significant appeal and continues to be a topic of active research (see Section 6.2). Early models suggested that intense frictional heating would quickly vaporize pore water trapped in the fault zone and lead to high fluid pressure and low effective normal stress (Lachenbruch, 1980). More recent analysis has focused on the

FIGURE 8 Inferred shear strength versus depth on SAF for possible fault zone constituent minerals. Heat flow and stress orientation constraints are indicated by linear strength increase with depth.

possibility that large earthquakes propagate in a pulse-like mode in which dynamic normal stresses unclamp the fault and allow slip at low shear stress (Heaton, 1990; Brune *et al.*, 1993; Ben-Zion and Andrews, 1998). Although these explanations are appealing, they only apply to dynamic slip and do not explain low heat flow along the creeping portion of the SAF in central California which appears to accommodate slip without large earthquakes.

Elevated fluid pressure is known to reduce fault strength (Hubbert and Rubey, 1959) and has been demonstrated to induce seismicity through the reduction of effective normal stress during fluid injection (Raleigh *et al.*, 1976) and reservoir impoundment (Talwani, 1976) (also see Chapter 37 of this volume). Furthermore, fluid overpressured zones, trapped fluids, and pore fluid compartmentalization are commonly observed in boreholes drilled for petroleum exploration and development (Hunt, 1990; Powley, 1990). If fluid migration is localized along faults and mineral precipitation and veining occurs, permeability will decrease and could lead to sealing and isolated fluid compartments. With time, faults can become barriers to flow and time-dependent compaction or dehydration reactions can lead to pore pressure buildup. The steady increase of fluid pressure can eventually lead to hydrofracture of the compartment seal and the escape of fluid. This cycle of slow fluid pressure buildup and then sudden pressure release has in fact been incorporated into a variety of episodic fault models (Sibson, 1981, 1992; Sleep and Blanpied, 1994; Fenoglio *et al.*, 1995; Lockner and Byerlee, 1995; Miller *et al.*, 1996).

The crust surrounding the SAF appears to be in compression (relative motion of Pacific and North American plates suggests a small component of convergence along the SAF) and is stressed critically for thrust failure in some areas such as the central Coast Ranges. Under these conditions, in order to avoid hydrofracture, the pore pressure must be less than or equal to a critical value

$$p_{cr} = \sigma_{Hmax} - (\sigma_{Hmax} - \sigma_{Hmin}) \cos \psi \sin(\psi - \phi_f) / \sin \phi_f \quad (15)$$

where ϕ_f is the friction angle and $\psi = ((\pi/2) - \beta)$ in Eqs. (4) and (5)] is the angle between the fault normal and the maximum horizontal stress σ_{Hmax} (Rice, 1992). Ignoring cohesion, for friction coefficients $\mu = \mu_f = 0.6-0.9$, Eq. (15) requires that p will exceed μ_{Hmin} and lead to hydrofracture when ψ is less than $30-40^\circ$. Thus, provided the stress state is homogenous across the fault zone, the observed high angle for σ_{Hmax} along the fault is an argument against high pore pressure as an explanation of the weakness of the SAF.

This problem of excessive pressure buildup resulting in hydrofracture before fault slip occurs can be avoided for a mature fault zone which is wide enough to sustain a pore pressure gradient. Two mechanisms have been proposed for producing pore pressure which increases from the fault zone boundaries to the fault core axis. Byerlee (1990, 1993)

suggested that for fine-grained fault gouge (especially containing hydrophilic clays or other minerals) a threshold pore pressure gradient may exist below which pore fluid will not flow. In this case, time-dependent compaction of the fault gouge material would lead to the establishment of a stable pore pressure profile in which pressure increases toward the fault zone axis by an amount equal to the threshold pressure gradient of the gouge material. For small faults that have narrow gouge zones, this pressure gradient is inconsequential. However, for mature fault zones such as the San Andreas where the fault zone may be hundreds of meters wide, a stable pore pressure profile could exist in which there is no pore fluid flow between, for example, hydrostatic pore pressure on the boundaries of the fault zone and near lithostatic pore pressure along the fault zone axis. In this case, the fault would have essentially no shear strength. In this model, rising fluid pressure within the fault zone leads to loss of strength and yielding. The resulting deformation changes the magnitude and orientation of principal stresses within the fault so that the pore pressure remains less than the minimum principal stress everywhere.

Rice (1992) proposed an alternative model in which a deep-rooted fault such as the San Andreas would have higher permeability than the surrounding crustal rock and would act as a conduit for the upward migration of mantle-derived fluids. Based on laboratory observations that permeability is highly sensitive to effective mean stress (Brace *et al.*, 1968; Pratt *et al.*, 1977; Brace, 1978; Morrow *et al.*, 1994), Rice's model predicts that pore fluid pressure at the base of the fault zone increases until a steady-state condition is achieved in which fluid flows up the axis of the fault zone and leaks out into the surrounding country rock. In this case, as in Byerlee's model, a pore pressure gradient is established between the fault zone axis and the country rock, so that pore pressure in the interior of the fault zone can be near-lithostatic and at the same time be less than the minimum principal stress throughout the fault zone. These models must be verified by direct observation over many years since drilling into the fault zone is likely to disturb the local pore pressure and the re-establishment of a steady-state condition may be quite slow.

We now examine the fourth possibility that the San Andreas is weak strictly as the result of the fault gouge mineral strength. Although few minerals have frictional strengths significantly greater than $\mu = 0.85$, there are numerous examples of potential fault gouge materials that are weaker than Byerlee's law. For example, biotite (Kronenberg *et al.*, 1990) and graphite (Morrow *et al.*, 2000) have an easy cleavage and weak interlayer bonding which results in a low shear strength. In this regard, Byerlee's law can be thought of as a limiting shear strength for deformation of a granular aggregate or Coulomb material between rigid driving blocks. When weak minerals are sheared in similar geometries, frictional strength can be ranked according to mineral bond strength (Morrow *et al.*, 2000). Laboratory determinations of

friction for a range of rock types and minerals that are found in fault zones are summarized in Figure 9. Most mineral strengths in Figure 9 with friction below 0.7 have been tested wet since the presence of pore water can contribute significantly to low strength of some minerals. Good examples are smectites (montmorillonite clay) and chrysotile (serpentine) which have a strong affinity for interlayer or adsorbed water and exhibit remarkably low shear strength when wet (Moore *et al.*, 1983, 1996, 1997; Reinen *et al.*, 1991, 1994; Morrow *et al.*, 1992). In this case, increased temperature or mean stress tends to drive off adsorbed water and leads to increased shear strength (Fig. 9) (Moore *et al.*, 1997).

Montmorillonite is an expandable clay that, because of its low shear strength and general abundance, has been suggested as a contributor to low strength faults (Wu *et al.*, 1975; Wang, 1984; Morrow *et al.*, 1992). At room temperature wet montmorillonite has a coefficient of friction of about 0.2. As we mentioned, this low shear strength is the result of weakly bonded interlayer water attracted to the charged surfaces of the clay platelets. Under similar conditions, dry montmorillonite has $\mu \sim 0.4$ (Moore *et al.*, 1983; Morrow *et al.*, 2000). Consequently, at shallow depths (low pressure and temperature) montmorillonite comes close to satisfying the heat flow and stress orientation constraints for the SAF. However, shear strength tests on montmorillonite at conditions representing increasing burial depth show two effects. First, the higher temperatures and pressures associated with the deeper fault

zone tend to drive off the interlayer water and result in increased frictional strength. Secondly, montmorillonite becomes chemically unstable with increasing temperature and first dehydrates and then reverts to illite by approximately 400°C (Wu *et al.*, 1975; Wang, 1984). Illite has a significantly higher shear strength than montmorillonite and cannot satisfy the weak SAF constraints. Above approximately 100°C mixed-layer montmorillonite/illite clay may be expected in the fault zone (Freed and Peacor, 1989; Meunier and Velde, 1989). As a result, the deeper part of the fault is expected to rapidly increase in strength (Fig. 8).

Another potential candidate for limiting shear strength of the San Andreas fault is the chrysotile form of serpentine. Due to its strong affinity for adsorbed water, chrysotile is one of the weakest likely fault zone minerals (room temperature friction is $\mu \sim 0.2$ and decreases to a minimum strength of $\mu \sim 0.1$ at 100°C (Moore *et al.*, 1996, 1997). Furthermore, chrysotile is associated especially with the creeping section of the SAF in central California (Coleman and Keith, 1971; Irwin and Barnes, 1975). However, as in the case of montmorillonite, chrysotile also increases strength with temperature and pressure as shown in Figures 8 and 9. Although it is possible that other less-common minerals exist that may retain a low coefficient of friction to relatively high temperature (i.e., brucite, Morrow *et al.*, 2000), the general trend of increasing strength of common fault gouge constituents with increasing pressure and temperature makes it unlikely that a weak San Andreas fault zone can be explained solely in terms of mineralogy.

In summary, a self-consistent workable model for a weak San Andreas fault can be based on elevated fluid pressure. A combination of elevated fluid pressure and inherently weak fault-zone mineralogy should also satisfy the heat flow constraints and has the advantage that less severe pore fluid overpressures are required. Dynamic weakening can also contribute to reduced frictional heating and needs to be understood more fully. It is possible that all three mechanisms will be found to play significant roles in contributing to the apparent low strength of the San Andreas fault.

3.3 Brittle-Ductile Models

Laboratory observations suggest earthquakes should be limited to conditions where the differential stress does not exceed the ductile flow strength of rocks, because under most circumstances ductile deformation, deformation which allows large strain without loss of strength, precludes dynamic stress drop. Ductile yield strength, equal to the differential stress σ_d during yielding, rapidly decreases with temperature as follows from the creep flow law

$$\dot{\epsilon} = A \sigma_d^n \exp\left(\frac{-E}{RT}\right) \quad (16)$$

FIGURE 9 Frictional resistance ($\tau/\sigma_{n,eff}$) plotted for crushed layers of common rocks and minerals sheared between granite or sandstone driving blocks.

FIGURE 10 The brittle ductile transition and the depth extent of seismicity. (a) Brittles and ductile strength. (b) Seismicity from the central creeping section of the San Andreas fault. (c) World seismicity for events with body wave magnitude $m_b > 5$.

where R is the gas constant, E is the activation energy, n is a dimensionless constant, and A is a constant ($\text{MPa}^{-n} \text{sec}^{-1}$). Seismicity occurs at conditions where brittle strength [Eq. (14)] is lower than Eq. (16) (Fig. 10a). Diagrams, originated by Goetze and Evans (1979), such as Figure 10, where quartz strength is assumed representative of the continental crust and olivine of oceanic crust, can explain the general depth dependent features of natural seismicity (Fig. 10b and c). However uncertainties in the form of the flow law (Brace and Kohlstedt, 1980; Kirby, 1980), uncertainty of the Earth's temperature gradient and the strain rate dependence of Eq. (16) do not allow the strength or other material properties to be well constrained by natural seismicity.

An additional consideration in determining the depth extent of seismicity in the Earth is to allow for the possibility of aseismic fault slip within the brittle field. Studies of frictional sliding indicate that faults can slide stably under some circumstances. Thus it is possible that the maximum depth extent of seismicity is not determined by the transition to predominately ductile deformation but instead by a transition from unstable to stable frictional sliding (Scholz, 1990; Blanpied *et al.*, 1991, 1995; Chester, 1994, 1995).

4. Frictional Instability and Earthquakes

If earthquakes correspond to slip on preexisting fault surfaces, as opposed to failure of intact rock, then the conditions leading to unstable fault slip are relevant to studies of earthquake nucleation. Unstable sliding is only possible if fault strength drops following the onset of slip so that stored elastic energy

from the surrounding rock can be used to drive the instability. The simplest description of fault rheology [Eq. (2b)] represents shear resistance strictly in terms of (effective) normal stress and precludes the possibility of weakening due to time-, temperature-, slip-, or slip rate-dependent processes. Under proper conditions, Eq. (2b) can allow for instability driven by increasing pore fluid pressure or possibly a rotation of the stress field loading a fault, but there are clear examples of fault instability in laboratory tests that do not involve these mechanisms. For frictional slip, instability depends only indirectly on the absolute level of strength. Rather, instability depends on inequality between fault strength and the stress available to shear the fault, which is supplied by the loading system. In basic terms, elastic energy is stored in the surrounding rock as tectonic processes load the brittle crust. When the strength of a fault is reached, sliding will commence and stored elastic energy is converted into frictional heat or surface energy as the fault rock is crushed. If an increment of slip on the fault surface reduces the fault strength faster than the driving stress is reduced, an unstable condition develops in which fault slip can accelerate into an earthquake and some of the stored elastic energy is radiated as seismic waves (Byerlee, 1970; Dieterich, 1979). In the laboratory, the test sample, piston, and load frame store elastic energy just as the brittle crust stores energy around a fault. Steady loading followed by dynamic fault slip is referred to as the “stick-slip” cycle and has been proposed as the laboratory counterpart of the earthquake cycle (Fig. 11) (Brace and Byerlee, 1966). Indeed laboratory stick-slip events are similar to earthquakes and if considered in terms of the dimension of rupture, earthquakes and other rock seismic faulting events form a continuum over at least 10 orders of magnitude. Great earthquakes occur on faults with linear

FIGURE 11 Stick-slip. Frictional strength vs. time during sliding on initially bare surfaces of Westerly granite at room temperature, 50 MPa confining pressure and $0.1 \mu\text{m sec}^{-1}$ loading velocity. The onset of detectable slip (t_{onset}) and the peak stress (t_{peak}) differ from the failure time (t_{fail}). Unstable slip shown by vertical line segments. The inset shows the spring and slider block model appropriate for laboratory experiments.

dimensions of hundreds of kilometers, whereas microseismicity and mining rock bursts represent fault instabilities spanning meters to tens of meters. Typical laboratory faults have lengths of 0.01–0.1 m and for specialized test machines have 2 m fault length (Okubo and Dieterich, 1984). At an even smaller scale, microcracking and associated ultrasonic acoustic emissions occur over a range from micrometers to millimeters and have been used as a laboratory analogue for many earthquake phenomena (Lockner, 1993a).

The elastic energy which drives instability can lead to a net drop in stress as shown from direct high speed stress measurements recorded during model earthquakes (Okubo and Dieterich, 1981, 1984, 1986; Lockner *et al.*, 1982; Lockner and Okubo, 1983; Ohnaka and Kuwahara, 1990). The simplest idealization of this stress drop is static and dynamic friction (Jaeger and Cook, 1971; Rice and Tse, 1986; Scholz, 1990), that is, a fault at rest has static friction represented by Eq. (2b) or (12) but once it begins to slip, strength drops immediately to a characteristic dynamic friction level. This concept proves to be unrealistic when applied to rupture nucleation due to the assumption of an abrupt change in fault strength (Ruina, 1983); strength drop for real materials is not instantaneous, and requires an apparent time or displacement weakening. An improvement over the static and dynamic friction model which well represents many aspects of the laboratory observations (Okubo and Dieterich, 1984, 1986; Ohnaka *et al.*, 1986;

Ohnaka and Kuwahara, 1990) is the incorporation of strain weakening, also known as displacement or slip weakening. This slip-weakening behavior has been described theoretically (Andrews, 1976; Rice, 1980; Rudnicki, 1980) and has also been confirmed experimentally for brittle failure of intact laboratory samples (Rice, 1980; Wong, 1982b; Lockner *et al.*, 1991) (see Section 4.2). In this case, stress decreases from static to dynamic friction over a characteristic displacement d_c or a characteristic strain $\varepsilon_c = d_c/w$, where w is the thickness of the deforming layer. Simple slip weakening functions include linear and exponential decay, and because of their mathematical simplicity, are useful in dynamic rupture propagation models.

If the elastic stiffness of the loading system is expressed as $k = d\tau/d\delta$, where δ is fault slip, then a requirement for instability at constant normal stress can be expressed in terms of a critical stiffness (Dieterich, 1979)

$$k_c = \frac{d\mu}{d\delta} \sigma_n \approx \frac{\Delta\mu \sigma_n}{d_c} \quad (17)$$

where $\Delta\mu$ is the drop in coefficient of frictional resistance. A slip instability can then occur for $k < k_c$. This relation has been verified experimentally for samples containing well-characterized displacement weakening (Lockner and Byerlee, 1990). In laboratory experiments, stiffness is the combined stiffness of the intact portion of the sample and the testing apparatus, whereas in the Earth the stiffness is related to the elastic modulus of the rock and the geometry of the portion of the fault that is slipping (e.g., Byerlee, 1970; Walsh, 1971; Dieterich, 1978a, 1979).

4.1 Characteristics of Earthquake Nucleation

In the context of earthquake nucleation, failure criteria such as Amontons' law establish a yield stress but are unable to explain premonitory phenomena such as creep or rupture nucleation. Although some moment inversions of radiated seismic energy suggest that earthquakes have distinct nucleation and propagation phases (e.g., Ellsworth and Beroza, 1995, 1998), only the final, rapid slip portion of the nucleation phase can be studied with seismic wave analysis. Attempts to measure natural fault slip during the early stages of fault nucleation have been unsuccessful (Johnston *et al.*, 1987; Linde and Johnston, 1989; Chapter 36 by Johnston and Linde). Given the high sensitivity of the strain meters in these studies, analysis of limited data suggests premonitory creep for moderate-sized earthquakes is restricted to nucleation patches that are tens of meters or less in linear dimension. Although field measurements of deformation have been unsuccessful in detecting the early strain associated with rupture nucleation, laboratory studies consistently demonstrate a characteristic accelerating slip phase that develops into the dynamic instability. Figure 11 shows the primary characteristics of

slowly nucleating laboratory failure. (1) Fault slip δ accrues as the fault is loaded at a constant rate, as evidenced by the deviation from linear increase in stress with time [shear stress on the fault $\tau = k(V_L t - \delta)$]. This behavior, if appropriate for natural earthquake failure allows for the possibility of detectable precursors such as strain or strain-related phenomena. For example, precursory strain should be associated with dilatancy (Nur, 1972; Scholz *et al.*, 1973) and a number of precursory phenomena measured in the laboratory [i.e., changes in acoustic velocity and attenuation (Lockner *et al.*, 1977, 1992a; Yanagidani *et al.*, 1985; Masuda *et al.*, 1990; Satoh *et al.*, 1990), Gutenberg–Richter *b*-value (Weeks *et al.*, 1978; Meredith *et al.*, 1990), electrical resistivity (Lockner and Byerlee, 1986), and permeability (Zoback and Byerlee, 1975; Morrow *et al.*, 1981)]. (2) Peak stress occurs before failure and post-peak accelerating slip is accompanied by slip weakening (e.g., Okubo and Dieterich, 1984; Ohnaka *et al.*, 1986; Ohnaka and Kuwahara, 1990; Lockner and Beeler, 1999) indicating no unique threshold failure stress. (3) Failure is delayed: there is lag time between the onset of detectable slip (t_{onset}) or the time of peak stress (t_{peak}) and the time of failure (t_{fail}). The reader is reminded that all of these features have direct counterparts in intact rock failure (Fig. 3 and, for example, Lockner *et al.*, 1992a; Lockner, 1998).

4.2 Slip-weakening Model and Unstable Rupture

Any mechanism that results in a loss in shear resistance that is more rapid than the unloading of the surrounding region has the potential for producing slip instability. One obvious example is the fracture of intact rock or, in the case of an irregular or segmented fault, the rupture of an asperity or competent step-over. Laboratory measurements (Fig. 1) indicate that strength reduction resulting from brittle fracture can be 20–50% of peak strength whereas strength loss associated with stick-slip of nominally flat, ground rock surfaces (see Section 4.3) is approximately 5–10% (Okubo and Dieterich, 1986; Ohnaka and Yamashita, 1989). Laboratory measurements have shown that dilatancy-induced pore pressure loss in a hydraulically isolated fault can lead to a 20% increase in effective normal stress (Lockner and Byerlee, 1994). Collapse of this open pore structure with continued deformation (Blanpied *et al.*, 1992) could repressurize pore fluid and provide a mechanism for triggering instability. The idealized flat, parallel fault surfaces used in laboratory tests to determine fault constitutive properties as described in the following section by Eqs. (18) are designed specifically to avoid complicating factors related to geometric fault complexity (and fluid pressure effects). In reality, natural faults are commonly irregular (fractal) over a broad range of scale (Brown and Scholz, 1985b; Scholz and Aviles, 1986; Power *et al.*, 1988; Moore and Byerlee, 1989, 1991). Some aspects of the geometric complexity of faults have

been explored (Andrews, 1989) but no framework exists for systematically analyzing this issue.

Ohnaka and co-workers developed an empirical model for unstable rupture that is described solely in terms of fault slip. The model is intended to describe the nucleation and growth of unstable rupture as measured on a biaxial press with granite sample dimension of $280 \times 280 \times 50$ mm (Ohnaka *et al.*, 1986). This apparatus, similar to but smaller than the 2-meter biaxial press (Okubo and Dieterich, 1981), has a fault surface that is large relative to the nucleation patch size for unstable rupture. The idealized slip instability is based on a slip-weakening model as discussed by Rice (1980) and Rudnicki (1980). The model includes a breakdown zone associated with an advancing crack tip in which shear stress τ near the crack tip is a function of shear displacement δ (Fig. 12a). High-speed records of the passage of a rupture front in a 2-meter fault are shown for comparison in Figure 12b (after Okubo and Dieterich, 1986). Note the characteristic stress rise as the rupture front approaches, followed by a rapid weakening to the dynamic sliding strength over displacement d_c . When shear resistance at a point on the fault is plotted as a function of fault

FIGURE 12 (a) Idealized process or breakdown zone associated with an advancing shear rupture. (b) An example of high-speed shear stress and fault displacement recordings during the passage of a shear rupture in granite on a 2-meter biaxial press.

slip (Rice, 1980) (Fig. 13), energy release rate G_{II} associated with the rupture propagation is represented by the area under the stress curve in excess of the frictional sliding resistance E_f . Similar results have been reported on the 0.4-meter biaxial press (Ohnaka *et al.*, 1986; Ohnaka and Yamashita, 1989; Ohnaka and Kuwahara, 1990; Yamashita and Ohnaka, 1991) (Fig. 13b). Scaling relationships have been proposed (Ohnaka and Shen, 1999) for critical slip distance, nucleation patch size and energy release rate assuming a dependence of nucleation on a characteristic surface irregularity size (Ohnaka and Yamashita, 1989; Ohnaka and Kuwahara, 1990; Yamashita and Ohnaka, 1991). The issue of fault heterogeneity arises in many contexts in earthquake processes including nucleation and stopping phases of earthquakes, abundance of high-frequency radiated energy, and earthquake statistics (Rice and Ben-Zion, 1996).

Fracture data for an initially intact sandstone sample are shown in Figure 13c where differential stress is plotted versus inelastic (or permanent) axial strain. This plot might represent, for example, the rupture of an asperity or interlocked region on a fault. Fracture nucleation coincides with the onset of rapid slip weakening. This portion of the breakdown curve is similar to the breakdown curve for the preexisting fault (Fig. 13b). The stress drop can be significantly greater for fracture of crystalline rock such as granite that has significant cohesion. The most notable difference between Figures 13b and c is the large amount of work done in loading the intact rock to peak stress. This work is expended in growing microcracks and in dense crystalline rock is accompanied by a volume increase and changes in a host of related material properties such as wave speed, electrical resistivity and permeability. Since these changes occur quasi-statically in response to tectonic loading, this is the effect most commonly appealed to in searching for premonitory phenomena.

This section ends with a comparison of time–position plots of fracture growth on a preexisting fault and in an intact rock. Figure 14a shows the growth of an instability in a precut granite sample with a 0.4-meter fault (Yamashita and Ohnaka, 1991). Solid circles denote the time the shear stress reaches the peak value, indicating the onset of instability. Open circles denote the time when the shear stress has dropped to the dynamic frictional stress level, indicating the passage of the breakdown zone. Note the finite width of the breakdown zone once the fracture is growing at near shear wave speed. Figure 14b is a space–time plot of acoustic emission rate recorded during shear fracture growth in an initially intact 0.2-meter long granite sample (Lockner and Byerlee, 1992). In this example, the fracture propagated quasi-statically as indicated by the slow advance rate of acoustic emission activity across the sample. The nucleation phase had a width of 2–3 cm in both the intact and faulted samples. Following nucleation, the narrow band of intense acoustic emission activity indicated the position of the advancing process zone.

4.3 Rate and State Friction Equations

The displacement-dependent rupture model described, for example, in Ohnaka and Shen (1999) describes fault conditions following the onset of rapid slip. Although it can account for failure characteristics such as post-peak loss of strength (Fig. 11), it does not address the characteristic prefailure deformation of slow, time-dependent creep (referred to as phase I in Ohnaka and Kuwahara, 1990). The dependent variables in frictional sliding, especially at slip rates of 10^{-9} – 10^{-4} m sec $^{-1}$, are more easily revealed in rate-stepping tests in a stiff testing machine ($k > k_c$) than in stick-slip or rupture nucleation experiments. Experimental measurements indicate the characteristic response of rock friction to changes in sliding velocity is somewhat complicated, consisting of two apparently additive log velocity-dependent effects: a positive, instantaneous dependence (direct effect) and a negative dependence which evolves approximately exponentially with displacement

FIGURE 15 Typical slip-rate dependence of fault strength for granite at 25 MPa normal stress and room temperature in response to an imposed change in sliding velocity. The loading velocity is decreased by an order of magnitude at displacement corresponding to the vertical dashed line. The net rate dependence $d\mu_{ss}/d\ln V$ is the sum of two opposing effects.

(evolution effect) (Dieterich, 1978b, 1979) (Fig. 15). These effects are generally small and of similar magnitude (typically a few percent of the total friction for a decade change in velocity (Blanpied *et al.*, 1998a). Since the effects are opposite in sign, they tend to cancel and the net dependence on slip velocity is even smaller and can be either positive or negative (Dieterich, 1978b, 1979; Tullis and Weeks, 1986).

The detailed response of fault frictional strength, at room temperature and modest normal stress (typically 5–200 MPa), to changes in sliding velocity, whether during rate-stepping tests or during stick-slip sliding, can be well described by what are usually referred to as rate and state variable constitutive equations, developed by Ruina (1983) as a generalization of equations of Dieterich (1978a, 1979),

$$\mu = \mu_0 + a \ln \frac{V}{V_0} + b \ln \frac{\theta V_0}{d_c} \quad (18a)$$

$$\frac{d\theta}{dt} = 1 - \frac{V\theta}{d_c} \quad (18b)$$

(Rice and Ruina, 1983; Ruina, 1983). Here μ_0 is the frictional resistance to slip at an arbitrary reference sliding velocity V_0 . μ_0 can be thought of as the first order frictional strength, such as described by Eq. (2) or (12). The other two terms in Eq. (18a) are the rate and state dependencies which are second order. The $a \ln(V/V_0)$ term describes the instantaneous rate dependence of strength (direct effect in Fig. 15) and the last term in Eq. (18a) represents the state dependence (evolution effect in Fig. 15). As written here, θ is the “state variable,” having the dimension of time. The form of θ prescribed in Eq. (18b) is one of a number of empirical equations that have been used in this context. [See Linker and Dieterich (1992) and Ruina (1983) for detailed discussions of the different forms of state and their properties.] The steady-state value of state, as deduced from Eq. (18b) is $\theta_{ss} = d_c/V$. When substituted in Eq. (18a) this defines the

steady-state rate dependence of fault strength $d\mu_{ss}/d\ln V = b - a$ which determines the sliding stability.

In the case where the dependence of steady-state frictional strength on the logarithm of sliding velocity is negative ($d\mu_{ss}/d\ln V < 0$), any perturbation that causes the fault to accelerate will lead to a loss of strength and will encourage further slip acceleration. In this case, slip instability is possible. Conversely, for neutral or positive rate dependence ($d\mu_{ss}/d\ln V \geq 0$) sliding will tend to be stable (Rice and Ruina, 1983). Linearized perturbation analysis of Eq. (18) (Rice and Ruina, 1983; Ruina, 1983) results in an expression for critical stiffness analogous to Eq. (17)

$$k_c = \frac{d\mu_{ss}}{d\ln V} \frac{\sigma_n}{d_c} \quad (19)$$

where μ_{ss} is the steady-state frictional resistance and d_c is the characteristic displacement of the evolution effect. Accordingly, instability is favored by more negative values of $d\mu_{ss}/d\ln V$ and by low values of k (more compliant loading systems) (Rice and Ruina, 1983; Gu *et al.*, 1984).

Laboratory measurements of rate dependence have been conducted using two-fault configurations: initially bare rock surfaces which consist of ground, flat, parallel rock which has been roughened with a coarse (typically 60–80 grit) abrasive, and simulated gouge layers which consist of powdered rock flour (typically $<90\mu\text{m}$ diameter) sheared between rigid blocks. The rate dependence of quartzo-feldspathic rocks, on which the constitutive relations Eq. (18) were based, can depend on whether or not the fault zone contains a thick gouge layer. Thick quartzo-feldspathic gouge layers have positive rate dependence unless shear displacement becomes localized within the layer (Dieterich, 1981; Marone and Kilgore, 1993) (also see review by Marone, 1998). Conversely initially bare rock surfaces of quartzo-feldspathic rock (Dieterich, 1978b; Tullis and Weeks, 1986) are rate weakening. In our review of rock friction measurements relevant to earthquakes we focus primarily on measurements that relate directly to frictional instability. We have therefore omitted studies on the frictional properties of gouge layers which show variability in the sign of the rate dependence (see summary by Beeler *et al.*, 1996), we focus predominately on the results from rate-weakening experiments on initially bare rock surfaces. Slip between such surfaces remains localized even at large displacement (Beeler *et al.*, 1996) and such faults show little tendency for fault zone width growth after an initial period of rapid wear (Biegel *et al.*, 1989) because they are flat at long wavelengths [see Power *et al.* (1988) and as discussed below].

In contrast to experimental faults, a continually expanding fault zone thickness is expected for natural faults (Robertson, 1983). For example, the San Andreas fault zone, with total offset of hundreds of kilometers, has a thickness of as much as a kilometer in places (Chapter 29 by Sibson). Increased thickness of natural faults may result from geometrical and

dynamic effects during shear. Natural rock surfaces such as fracture and joint surfaces have a fractal roughness (Brown and Scholz, 1985a). As a result, increasing displacement of an initially matched shear fracture (proto-fault) leads to an increasing volume of mismatched surface irregularity and therefore increasing wear material (gouge) with displacement (Power *et al.*, 1988). During earthquake slip, large dynamic stresses that develop in front of an advancing shear rupture during propagation may be higher on off-fault planes than on the fault plane itself (Rice, 1980). These high stresses may induce branching or off-fault deformation which may lead to nonplanar ruptures, fault surface roughening and gradual growth of the damage zone with successive earthquakes. The experimental observations thus require that slip during earthquake nucleation is localized so that $d\mu_{ss}/d\ln V < 0$, even within very wide fault zones. At least in experiments to date on gouge-filled faults, fault slip at large displacement does not localize to the degree that the rate dependence is negative (Beeler *et al.*, 1996). It is not known how such localization arises in mature natural fault zones.

4.4 Origin of Delayed Failure in Friction and Fracture

The two opposing rate-dependent effects seen in rate stepping tests (Fig. 15) can be qualitatively related to the onset of failure in stick-slip experiments (Fig. 11) in a straightforward manner. Obviously, frictional failure requires that the rate weakening term exceeds the rate strengthening term for the stress to drop as slip accelerates. However, negative rate dependence alone leads to rapid failure following a threshold failure stress and therefore does not allow for delayed failure or precursory slip. It is the long duration of the acceleration to failure (Fig. 16) which most clearly distinguishes observed failure from failure predicted by simple static and dynamic strength. Prior to the peak strength, which occurs when the sliding velocity equals the loading velocity $V = V_L$, the sliding velocity increases (Fig. 16)

FIGURE 16 Acceleration to failure during slip of granite at room temperature and 50 MPa confining pressure.

and yet the stress on the fault also increases (Fig. 11) indicating that fault strength depends positively on sliding velocity. Thus this precursory creep during delayed failure is directly attributed to the direct effect (Fig. 15). A similar positive dependence of strength on deformation rate is seen during intact failure (e.g., Lockner, 1998). Delayed failure in response to stress perturbations, which is characteristic of both frictional failure and fracture, is consistent with natural observations of Omori aftershock sequences (Scholz, 1968b; Lockner, 1993a; Dieterich, 1994) (see Section 4.5) and other triggered seismic phenomenon (Gomberg *et al.*, 1998) in which failure is delayed following a stress increase.

Brittle fracture at high normal stress is involved in both abrasion during frictional sliding of bare fault surfaces and grain fracture during shearing of granular gouge layers. Therefore, all kinds of experimental shear deformation in the brittle field should share characteristics associated with fracture. Fracture theory as well as experimental evidence suggest log rate dependent resistance during nucleation of a single fracture. The stress–inelastic strain relation for subcritical fracture (i.e., slow, stable fracture growth at stress intensity less than the critical value as discussed in Section 2.3.2), results from equating strain rate (equivalently velocity V) resulting from crack propagation to the rate of chemical reaction at the crack tip (Lockner, 1993b, 1998) where reaction rate is

$$v = v_0 \exp\left(\frac{-E + \Omega\sigma - \Omega_m\gamma/\chi}{RT}\right) \quad (20)$$

(e.g., Charles and Hillig, 1962). E is the activation energy, Ω is the activation volume, Ω_m is molar volume, γ is the surface energy, χ is the radius of curvature of the tip, v_0 is a constant, R is the gas constant, T is temperature and σ is the stress at the crack tip. The stress term is akin to the pressure dependence normally associated with an activation volume, such that the reaction rate is faster if the stress is elevated. As has been suggested by numerous authors (see review by Costin (1987)), this stress sensitivity of crack propagation rate likely underlies the established creep-like behavior of rock at low temperature (Scholz, 1968a) and the log rate dependence of the failure stress of intact rock (e.g., Lockner, 1998). Based on consideration of Eq. (20), and due to the involvement of fracture in frictional sliding, the subcritical component of fracture is a likely cause of the instantaneous positive rate dependence of rock friction.

4.5 Implications of Delayed Failure

Laboratory observations of delayed failure predict that stress changes affect the timing of earthquakes, and many natural observations of delayed failure are consistent with these predictions. For example, assuming that aftershocks result from a stress change superimposed on a constant tectonic loading

rate, Omori aftershock sequences indicate that the sensitivity of an aftershock source fault to stress depends on its temporal proximity to failure. That is, because aftershock rates immediately following a main shock static stress change are higher than they are at later times, faults closer to failure are advanced toward failure by a different amount than those that are far from failure. Such a time dependence of aftershock rates follows directly from Eqs. (18) (Dieterich, 1994). Assuming, based on the results of studies of static stress change (Stein and Lisowski, 1983; Harris and Simpson, 1992; Reasenber and Simpson, 1992), that aftershock failures are triggered by a stress increase and that ongoing tectonic loading provides a constant rate of stress increase, then seismicity rate r as a function of time t following an increase in shear stress $\Delta\tau$ is

$$r(t) = \frac{r_0}{1 - [1 - \exp(-\Delta\tau/a)] \exp(-\dot{\tau}t/a)} \quad (21)$$

where r_0 is the seismicity rate prior to the stress change, $\dot{\tau}$ is the stressing rate, and a is the constitutive parameter which scales the size of the direct effect in Eqs. (18) (Dieterich, 1994). Equation (21) predicts an Omori decay consistent with field observations (Fig. 17); a similar prediction was made by Scholz (1968b) who considered aftershocks as small fracture events, the natural analogue to acoustic emissions, instead of unstable slip of pre-existing faults.

Delay between the application of a stress change and failure, such as seen in laboratory experiments and predicted by constitutive Eqs. (18), are also consistent with the lack of tidal triggering of nonvolcanic earthquakes. Because daily variations in stress due to tidal forces (0.001–0.004 MPa) greatly exceed the daily accumulation of tectonic stress, earthquake occurrence would be strongly correlated with the tides if failure coincided with a stress threshold [e.g., Eq. (2)].

FIGURE 17 Time-dependent effects. Seismicity rate following a stress step from Eq. (21). The constitutive equation in this calculation is a simplification of Eq. (18). Seismicity rate follows an Omori decay and returns to the background rate over a characteristic time $t_a = a\sigma_n/\dot{\tau}$ (Dieterich, 1994).

However, analysis of natural occurrence suggests weak (Vidale *et al.*, 1998) or no (Heaton, 1982; Hartzell and Heaton, 1989) correlation between earthquakes and Earth tides. Numerical simulations of combined tectonic and tidal loading of fault populations obeying Eqs. (18) suggest that failure is insensitive to stress change with the amplitude and frequency of the tidal stress (Dieterich, 1987). Similar conclusions are reached from stick-slip experiments where constant loading was modulated by a small amplitude periodic signal. Correlation between the periodic loading and the time of failure occurred when the periodic amplitude was 0.05–0.1 MPa (Lockner and Beeler, 1999). Simple extrapolation of this result to the Earth suggests that approximately 1% of earthquakes on the San Andreas fault should be correlated with the tides; a result that is consistent with absent or weak correlations in field data.

4.6 Limits of Frictional Instability Predicted by Laboratory Observations

The rate and state variable constitutive Eqs. (18), which well describe many laboratory observations, can qualitatively explain a wide range of averaged seismic observations, e.g., realistic earthquake cycles (Tse and Rice, 1986), Omori aftershock sequences (Dieterich, 1994), the lack of tidal triggering of earthquakes (Dieterich, 1987; Lockner and Beeler, 1999), variations in stress drop with recurrence and loading velocity (Gu and Wong, 1991), foreshocks and earthquake clustering (Das and Scholz, 1981; Dieterich and Kilgore, 1996), earthquake afterslip (Marone *et al.*, 1991), precursory slip (Dieterich, 1994), and remotely triggered earthquakes (Gomberg *et al.*, 1997, 1998). Most important for frictional instability to be a viable explanation for natural seismicity is that transitions from stable (aseismic) and unstable (seismic) frictional sliding seen in experiments correspond to the depth range of observed seismicity. For example, seismicity on the San Andreas fault system is most active between about 4 and 15–20 km (Fig. 10). Two recent complementary experimental studies of quartz gouge and granite gouge attempt to directly predict the depth extent of seismicity by determining the rate dependence of frictional strength at temperatures spanning the entire seismogenic zone (Blanpied *et al.*, 1991, 1995; Chester and Higgs, 1992; Chester, 1994, 1995).

At the top of the seismic zone, corresponding to low temperature, the rate dependence of granite frictional strength is positive, in agreement with room temperature experiments (Byerlee and Summers, 1976; Solberg and Byerlee, 1984; Morrow and Byerlee, 1989; Marone *et al.*, 1990). The rate dependence of granite gouge undergoes a transition to rate weakening between 25 and 50°C (Blanpied *et al.*, 1991, 1995) (Fig. 18). However when converted to depth this prediction corresponds closely to the field observations of a seismic/aseismic transition at around 4 km only if the loading rates are orders of magnitude faster than the plate motion rate on the

FIGURE 18 Wet frictional strength and rate dependence over a wide range of temperature. (a) Westerly granite (Blanpied *et al.*, 1995). (b) Similar plot showing the fit to the data of Chester (1994) for quartz.

San Andreas. A similar conclusion is reached from application of the quartz data. Quartz does not show rate strengthening at the lowest strain rate and the lowest temperatures (Chester and Higgs, 1992), although thicker gouge layers are rate strengthening at room temperature and slightly elevated temperature (Marone *et al.*, 1990; Chester, 1994). Another explanation of the aseismic to seismic transition, that the depth extent of a thick gouge-filled fault zone controls the lack of shallow seismicity (Marone and Scholz, 1988; Marone *et al.*, 1991), is consistent with field evidence. However, the Marone study is based on data at sliding velocities much higher than plate motion rates and does not consider the temperature dependence observed in the Chester and Blanpied studies.

At higher temperatures, a lower seismic/aseismic transition is also predicted from the laboratory data. However, the depth of the transition is not fully consistent with observed seismicity. Blanpied *et al.* (1991, 1995), Chester and Higgs (1992), and Chester (1994, 1995) studied friction in the presence of water at temperatures up to 600°C. In the Blanpied study, steady-state rate dependence of granite was determined at 100 MPa water pressure and 400 MPa confining pressure. The Chester study involved stress relaxation tests at 100 MPa water pressure and 250 MPa confining pressure. Both studies show a broad range of temperatures where the rate dependence is measured or inferred to be negative, permitting frictional

instability from 25–350°C for sliding velocities of 0.1–0.01 $\mu\text{m sec}^{-1}$ (e.g., Blanpied *et al.*, 1991) (Fig. 18). At higher temperatures, ductile processes such as solution transport creep (pressure solution) begin to affect the strength of load-bearing contacts in the experimental fault zones (Chester and Higgs, 1992). This high temperature regime shows strong velocity strengthening and stable sliding. Although these experiments imply a seismic zone that corresponds roughly to natural observations, the sliding rates, corresponding to loading rates on natural faults, used in the steady-state sliding experiments are 10–100 times faster than typical plate motion on the San Andreas fault. If the results of these studies are extrapolated in strain rate to an appropriate natural condition, the base of the seismogenic zone would occur at about 180°C for quartz (Fig. 18b) and about 240°C for granite (Fig. 18a). This is in agreement with the temperature at the base of the seismogenic zone for the Landers rupture, but much less than the 350–400°C inferred for the San Andreas based on heat flow measurements (Williams, 1996). Thus, while existing experimental studies qualitatively predict many aspects of natural seismicity, the field observations are not matched closely. Better knowledge of fault zone mineralogy and the rate dependence of more typical fault zone gouges (e.g., clays and other alteration products) at these deeper hypocentral depths would be useful in providing more accurate representation of fault properties, particularly in instances such as the San Andreas fault where fault strength may deviate significantly from that of quartzo-feldspathic (Byerlee's law) materials. The effects of fluids and the role of fluid pressure at elevated temperatures, not taken into account in the friction studies we have discussed so far, may also be important in frictional failure in the Earth.

5. Pore Fluid Effects

Pore fluid can affect fault failure strength in two fundamental ways: (1) pore fluid pressure can reduce the effective normal stress via the effective pressure law Eq. (7) and therefore reduce the failure shear stress in the brittle portion of the crust [Eq. (2) or (12)] as discussed above in the context of fracture, and (2) pore fluid at elevated temperatures can lead to dissolution and precipitation or other chemical reactions which may alter fault strength (see summary by Hickman *et al.*, 1995). Interest in pore fluids has arisen because dry friction cannot explain all of the field observations of faulting. For a classic example, the lateral dimensions of thrust sheets are large enough relative to sheet thickness that the force necessary to overcome the frictional resistance is sufficient to break the hanging wall block unless high pore fluid pressure reduces the effective stress on the sliding surface (Hubbert and Rubey, 1959). Recently, models involving elevated fluid pressures have been proposed to explain the apparent weakness of the San Andreas (Byerlee, 1990; Byrne and Fisher, 1990; Rice, 1992; Sleep and Blanpied,

1992; Lockner and Byerlee, 1995) (see Section 3.2). Presently there is also interest in the role of pore fluid pressure in Coulomb failure models [based on Eq. (2) or (12)] of triggered seismicity [see reviews by Harris (1998), Stein (1999) and Chapter 73 by Harris]. Although few laboratory studies have directly addressed the role of pore fluid in failure, some useful inferences can be drawn from studies of elastic coupling between stress and pore pressure (summarized in Section 5.1) and from experimental studies carried out on faults under conditions where no excess internal fluid pressure occurs (summarized in Section 5.2). Most evidence for the influence of chemical effects on faulting comes from field observations of healed fractures, pressure solution and veining, and alteration products (Power and Tullis, 1989; Parry and Bruhn, 1990; Parry *et al.*, 1991; Chester *et al.*, 1993; Bruhn *et al.*, 1994). The limited relevant laboratory observations summarized in Section 5.3 do not yet make a strong case for chemical effects in earthquake mechanics.

5.1 Role of Poroelastic Effects in Models of Coulomb Failure (New and Provisional Results)

Studies of triggered seismicity have used the stress changes produced by slip of a large earthquake to explain the spatial distribution of subsequent earthquakes in the surrounding region. Such studies commonly assume that earthquakes in the surroundings obey the Coulomb failure criterion [Eq. (2)] and that changes in proximity to failure of a particular fault plane can be determined if the stress changes are known. The change in proximity to failure is the change in Eq. (2) due to earthquake-induced stress

$$\Delta\sigma_c = \Delta\tau - \mu_f(\Delta\sigma_n - \Delta p) \quad (22a)$$

Here, S_0 is assumed constant, and the effective stress law has been invoked. Positive values of $\Delta\sigma_c$ indicate that the fault plane in question is closer to failure, whereas for negative values the fault is farther from failure. The stress changes used to evaluate Eq. (22) are commonly calculated from dislocation models of the source earthquake slip, assuming the surroundings are linearly elastic. Although laboratory studies provide limits on μ_f (e.g., Byerlee, 1978), Δp must be estimated using some model of pore fluid response to stress change. In most studies of stress-triggered seismicity, pore pressure change is not considered explicitly and μ_f in Eq. (22a) is replaced by a free parameter,

$$\Delta\sigma_c = \Delta\tau - \mu' \Delta\sigma_n \quad (22b)$$

The spatial distribution of earthquakes is consistent with positive values of Eq. (22b) if $\mu' = 0.4$ (Stein, 1999).

Current experimental and field observations cannot provide constraints on the choice of appropriate pore pressure response models to use in studies of triggered Coulomb failure.

Experiments suggest that in many cases change in pore pressure in rock and soils is determined by the change in mean stress (Skempton, 1954; Roeloffs, 1996). For a homogeneous isotropic poroelastic medium (Rice and Cleary, 1976; Roeloffs, 1996), the relation between stress change and pore pressure change is

$$\Delta p = B \Delta \sigma_{kk} / 3 = B \Delta \sigma_m \quad (23)$$

where σ_{kk} indicates summation over the diagonal elements of the stress tensor and $\sigma_m = \sigma_{kk}/3$ is the mean stress. The parameter B is Skempton's coefficient, and is limited to the range $0 \leq B < 1$. Relatively sparse experimental determinations of B for rocks indicate a range from 0.5 to 0.9 for granites, sandstones, and marbles (Rice and Cleary, 1976; Roeloffs and Rudnicki, 1985; Roeloffs, 1996).

However, Eq. (23) is based on studies of intact rock samples, not faulted rock, and there are no analogous experimental measurements of the poroelastic response of fault zones. Because they may have accommodated large shear strains and are often associated with hydrothermal alteration, it is unlikely that the poroelastic properties of mature fault zones are identical to the surrounding country rock as assumed in Eq. (23). Cocco and Rice (2002) suggest an inhomogeneous isotropic poroelastic response model,

$$\Delta p = B' \frac{K'_u}{M'_u} \left[\frac{G' M_u}{G K_u} \Delta \sigma_m + \frac{G - G'}{G} \Delta \sigma_n \right] \quad (24)$$

Here the primed and unprimed constants are associated with the fault-zone and country rock, respectively; $M = \lambda + 2G$, $K = \lambda + 2G/3$, and G and λ are the Lamé elastic constants. According to Eq. (24), the poroelastic response of fault zones depends on changes in both mean stress and normal stress. In the case where $G = G'$, Eq. (24) reduces to Eq. (23); however if $G \gg G'$, as might be expected for mature fault zones, $\Delta p \propto \Delta \sigma_n$ (Cocco and Rice, 2002) [cf. Eq. (22b)].

Similarly, in the case where the fault zone is anisotropic, stress components other than mean stress may be important in determining the pore pressure response to stress change. For example, simulated laboratory faults, mismatched tensile fractures and natural joint surfaces have large fault-normal compliance (Brown and Scholz, 1985b) because normal stress is supported by a few highly stressed asperities. Although the orientations of fluid-filled fractures along active fault zones at depth are generally unknown, if natural faults and associated fault-parallel fractures have an asperity structure similar to mismatched joints and are hydraulically isolated from the adjacent country rock, then

$$\Delta p \propto \Delta \sigma_n \quad (25)$$

would be the expected pore fluid response (Cocco and Rice, 2002). In this case Eq. (22b) would be an appropriate Coulomb failure model.

While Eqs. (23), (24), and (25) are plausible models of poroelastic response, other measurements indicate that elastic stress–pore-fluid-pressure interactions are more complicated. For example, volumetric changes can be produced by changes in deviatoric stress alone, both in unfaulted (Wang, 1997; Lockner and Stanchits, 2002) and faulted rocks (Woodcock and Roeloffs, 1996). Furthermore, inelastic effects, discussed in the next section, may alter the pore fluid pressure response of seismic fault zones near failure (Segall and Rice, 1995, and references therein).

5.2 The Role of Dilatancy and Inelastic Pore Fluid Effects in Frictional Failure (New and Provisional Results)

Drained measurements of pore volume or fault thickness suggest that fault zone pore pressure will vary with velocity, time, and displacement during frictional sliding and frictional failure. This follows from measurements originally made of gouge volume or fault normal displacement during rate step tests on gouge layers by Morrow and Byerlee (1989), Marone *et al.* (1990), and Lockner and Byerlee (1994) and subsequently also for initially bare surfaces (Wang and Scholz, 1994; Beeler and Tullis, 1997) (Fig. 19a). Following a velocity change there can be both immediate and steady-state changes in dilation or compaction rate within the fault gouge layer. The steady-state changes in dilation or compaction due to displacement rate are generally small compared to changes in friction (Beeler *et al.*, 1996), but immediately after the velocity change can be large (Marone *et al.*, 1990; Sammis and Steacy, 1994). Much like strength evolution, porosity of the fault gouge evolves to steady state over a characteristic displacement. Beeler and Tullis (1997) have argued that rate-dependent changes in porosity are directly related to the state variable in Eqs. (18), at least for initially bare surfaces, based on similar time and slip dependencies between fault thickness and state. Compaction occurs even when the fault sliding rate is negligible, suggesting that fault zone thickness is time dependent (Fig. 19b). The time-dependent compaction under nominally static shear strain follows the same log linear form as fault strength under the same conditions (Dieterich, 1972) (Fig. 19b inset). After a shear zone compacts statically, subsequent shear induces dilatancy (e.g., Fig. 19c). The fault normal displacement δ_n resulting from opposing effects of linear shear-induced dilatancy and log time-dependent compaction can be represented by Eq. (18b) and

$$\delta_n = \delta_{n0} + \varepsilon \ln \frac{V_0 \theta}{d_c} \quad (26)$$

where compaction is reckoned positive, δ_{n0} is the steady-state normal displacement when $V = V_0$, and ε is the negative of the steady-state velocity-dependence of fault thickness $\varepsilon = -d(\delta_n)_{ss}/d \ln V_{ss}$ (Marone and Kilgore, 1993). In Eq. (18b), state changes exponentially with slip and linearly with time and when

FIGURE 19 Dilatancy during frictional sliding. (a) Changes in fault thickness (proportional to changes in porosity) with sliding velocity. (b) Time dependence of fault thickness. (c) Fault thickness as a function of slip following a hold test for bare surface granite and quartzite (unpublished data courtesy of T. Tullis).

used in Eq. (26) yields the linear slip and log time-dependent thickness changes required by the data (Fig. 19b and c). Equations (26) and (18b) lead to a rate-dependent response of fault thickness to changes in sliding velocity consistent with the observations (Fig. 19a). In experiments on initially bare surfaces, the characteristic displacement of thickness evolution following changes in sliding velocity is approximately equivalent to the characteristic displacement of strength evolution. This association between fault thickness or porosity with state is much less pronounced for thick, gouge layers (Beeler and Tullis, 1997), where the characteristic

displacement to recover strength differs from that to recover the porosity.

It should be noted that fault gouge porosity is sensitive to normal or mean stress and that laboratory tests have been carried out at either constant normal stress or constant confining pressure. Loading histories of natural faults may be considerably different from either constant normal stress or confining pressure (although the latter case of increasing normal stress with increasing σ_1 may be closer to the tectonic loading history experienced by thrust or strike-slip faults). Normal faulting may be preceded by a decrease in minimum compressive stress and normal stress. The importance of these naturally occurring stress paths and the effect that they may have on pore pressure and shear strength have not yet been properly explored.

Important implications of experimental observations of rate-dependent porosity change for earthquake nucleation have been considered by Segall and Rice (1995). They extended the original stability analysis of rate and state equations (Rice and Ruina, 1983; Ruina, 1983) to consider the role of pore pressure and conducted numerical simulations of earthquake cycles to determine the effects of pore pressure on strength and fault stability. In this analysis they ignore the small changes in steady-state displacement rate of dilation and assume a steady-state drained porosity

$$\eta_{ss} = \eta_0 + \varepsilon \ln \frac{V}{V_0} \quad (27)$$

where ε is a constant, and a dependence of porosity on state such that porosity evolves to steady-state over the state characteristic displacement d_c , consistent with Eq. (26) and with the laboratory observations. For an undrained porosity, the stiffness for unstable slip must be less than the critical value

$$k_c = \frac{\sigma_{n,eff}}{d_c} \frac{d\mu_{ss}}{d \ln V} - \frac{\varepsilon \mu_{ss}}{B d_c} \quad (28)$$

where B is a poroelastic constant (Segall and Rice, 1995). Thus, dilatant faults are found to be more stable in comparison to nondilatant faults; the critical stiffness predicted by Eq. (28) is less in comparison to Eq. (19) due to the additional dilatant term.

Numerical simulations of earthquake cycles using laboratory values of fault strength and porosity conducted by Segall and Rice (1995) do not lead simultaneously to high pore pressure and instability. Thus, to the degree that the Segall and Rice model reflects the dominant poromechanical interactions of fault zones, it implies that high pore pressure is an unlikely cause of the weakness of seismogenic faults such as the San Andreas. However, this conclusion is based on analysis of dilatancy observed during stable sliding of drained faults at room temperature and high porosity (e.g., 11–26%, Marone *et al.*, 1990), conditions which may not be representative of earthquake failure at seismogenic depths. In particular, Eq. (27)

requires that fault thickness (porosity) increases monotonically during failure and that the maximum fault zone porosity is determined by the peak velocity during unstable slip. These predictions are contradicted both by some soil mechanics observations, and by measurements of fault thickness during stress drop. When overcompacted soils are sheared at constant loading rate, porosity may not increase monotonically. Instead, the steady-state thickness can be reached by compaction (e.g., Mandl *et al.*, 1977). In experiments on thick gouge layers where shear stress is artificially reduced at the start of a static hold, stress drop is accompanied by compaction (Karner and Marone, 1998; Nakatani, 1998), presumably consistent with compaction during earthquake stress drop. Compaction accompanying stress drop has also been reported during stick-slip sliding (Beeler and Tullis, unpublished data).

The observations of compaction accompanying shear stress reduction have untested implications for the evolution of fault fluid pressure throughout the seismic cycle. Stress drop will lead to a reduction in effective normal stress under undrained conditions possibly providing a simple “dynamic weakening” of fault strength. This effect would occur at constant normal stress such as in strike-slip environments and may be significant in normal faulting environments where shear stress drop is accompanied by normal stress increase. On the other hand, following compaction, much larger dilatancy occurs during loading to failure (Nakatani, 1998) which should tend to stabilize sliding through dilatancy hardening. Constitutive equations describing the experimental observations have been proposed by Nakatani (1998). However, the implications that this rheological model has for fault stability have not yet been addressed.

5.3 Solution Mass Transport Phenomenon (New and Provisional Results)

Although hydrothermal studies of frictional slip at temperatures greater than 180–240°C and displacement rates corresponding to typical plate motion rates, indicate stable, pressure-solution-like deformation within a fault zone (Blanpied *et al.*, 1995; Chester, 1995), other solution mass transport phenomena such as overgrowths on load bearing contacts and fault zone sealing and compaction could operate at these conditions, and lead to rapid and large changes in fault zone material properties. Laboratory measurements of fault strength (Blanpied *et al.*, 1992) and fault strengthening (Fredrich and Evans, 1992; Karner *et al.*, 1997), and inferences of fault strength (S. Hickman, unpublished data) at hydrothermal conditions (>300°C) where solution transport phenomenon can be rapid, lead to two models where fault failure stress differs from the predictions of conventional rate and state friction. In the following sections we describe these two proposed mechanisms: (1) a solution mass transport compaction and fault sealing model and (2) a solution mass transport lithification model, and the experimental evidence that supports them.

5.3.1 Pressure Solution and Fault Sealing

If minerals are sufficiently soluble in water, then dissolution, transport, and precipitation can occur in response to gradients in chemical potential due to spatial variation of temperature, stress, or surface energy. Numerous studies have reported rapid reduction of permeability of rocks and joints (Moore *et al.*, 1994), and granular aggregates (Tenthory *et al.*, 1998) at such conditions. Additional studies have demonstrated rapid sealing due to flow along a temperature gradient (Summers *et al.*, 1978; Moore *et al.*, 1984; Vaughan *et al.*, 1985). In faulting experiments at 600°C, Blanpied *et al.* (1992) inferred permeability reduction so rapid that in the presence of shear induced compaction, effective pressure increased, leading to a 50% reduction in shear strength. The observations of reduced strength (Fig. 20) suggest a potential earthquake mechanism for weak faults where, within a fault zone hydraulically sealed with respect to its surroundings, shearing leads to compaction and increased fluid pressure. Instability is initiated when the fault failure strength is reached by the combined action of tectonic loading and effective stress decrease (Blanpied *et al.*, 1992), i.e., this failure mechanism differs from standard rate and state models in that porosity and $\sigma_{n,eff}$ are functions of time and displacement.

A qualitative instability model based by the observations by Blanpied and co-workers (Blanpied *et al.*, 1992; Sleep and Blanpied, 1992, 1994) is not unlike the Segall and Rice (1995) model, and accordingly, its potential for instability will be reduced in comparison to dry friction-based instability models through dilatancy and reduction in the critical stiffness. If dilatancy accompanies increases in sliding velocity (Morrow and Byerlee, 1989; Marone *et al.*, 1990; Lockner and Byerlee, 1994) during failure, the accompanying effective stress increase stabilizes the fault (dilatancy hardening) (Rice, 1975; Rudnicki and Chen, 1988; Lockner and Byerlee, 1994). Decreases in effective stress brought on by compaction during

FIGURE 20 Measured shear stress (upper graph solid, left axis scale), $\tau/(\sigma_n - p)$ (upper graph dashed, right axis scale) and pore pressure (lower graph) versus axial displacement for Granite gouge at 600°C and 400 MPa confining pressure.

loading to failure reduce the critical stiffness, stabilizing the fault as in Eq. (17) or Eq. (19). Compaction-induced instability models are untested, as they require creep compaction behavior that has not yet been observed experimentally at the appropriate temperatures (200–400°C). Theoretical studies of creep compaction instability are ambiguous. Sleep and Blanpied (1994) report such instabilities using faults with uniform rate and state-like properties, as do Lockner and Byerlee (1995) using a Burridge–Knopoff-type model with inhomogeneous properties. Dilatancy hardening results in a delay but not an inhibition of dynamic failure for the Lockner and Byerlee model. On the other hand, strict interpretation of the existing experimental compaction data from rate-stepping tests, albeit at much lower temperatures (discussed in Section 5.2) does not lead to both weakness and instability (Segall and Rice, 1995).

5.3.2 Lithification

It has been suggested that at hydrothermal conditions, rates of fault healing may be greatly enhanced due to lithification processes that are not present in room temperature friction experiments (Kanamori and Allen, 1986; Scholz *et al.*, 1986). Increases in static stress drop with recurrence for large and small repeating earthquakes may exceed the rate predicted by low-temperature friction (Kanamori and Allen, 1986; Scholz *et al.*, 1986; Nadeau and McEvilly, 1999; Beeler *et al.*, 2000), consistent with lithification. Accordingly, a fault-strengthening model based on this hypothesis would predict fault-strengthening rates that exceed those predicted by rate and state implementations of room temperature friction. Such rapid fault strengthening has been suggested to occur in experiments at elevated temperatures and hydrostatic pressure on quartz gouge at rates which exceed those observed at low temperature (Fredrich and Evans, 1992; Karner *et al.*, 1997). However, to achieve the apparent enhanced rate of strengthening, fault gouge must be loaded to failure at a lower temperature (230–235°C) than the healing temperature (500–800°C). Experiments where the healing and loading temperature are the same [636°C (Karner *et al.*, 1997)], as would be the case for faults in the Earth, show no time-dependent strengthening. The lack of time dependence indicates that these studies of fault strengthening at very high temperature may have limited relevance to natural earthquake failure. These studies are designed to measure healing due to local redistribution of material, i.e., dissolution from pore walls or fine or angular grains followed by deposition at grain contacts. More rapid or more significant cementation may occur due to mass transport of silica or calcite over large distances within a fracture network. Certainly quartz vein filling is a well-known example of this strength recovery process (Chapter 29 by Sibson).

Lithification processes other than pressure solution which may lead to fault strengthening can be induced at hydrothermal conditions where a reduction in surface energy, not a reduction in contact stress, drives solution mass transport

FIGURE 21 Fault strengthening inferred from contact area increase with time at hydrothermal conditions.

processes (Hickman and Evans, 1992). Recent experiments on single contacts in quartz at $T = 350\text{--}530^\circ\text{C}$, $P_c = P_{\text{H}_2\text{O}} = 150\text{ MPa}$ and non-zero contact normal stress indicate extremely rapid contact overgrowth (S. Hickman, unpublished data). Because of the controlled geometry and *in situ* monitoring, the mass flux as a function of time is known and the results can be extrapolated to other contact geometries. When extrapolated to a contact size typical for laboratory friction experiments, the contact area increase in these experiments greatly exceeds those of frictional strengthening (Fig. 21). The area increase is so great as to imply that fault zones subject to low effective stress may become entirely lithified during the interseismic period. In this case, the fault failure strength would rapidly approach the strength of an intact rock. However, the low contact stress in the experiments prevents easy extrapolation of these results to seismogenic conditions.

6. Dynamic Fault Strength

Although laboratory observations of frictional strength as represented by Eq. (19) have been applied to model the entire seismic cycle (e.g., Rice and Tse, 1986; Boatwright and Cocco, 1996), this assumes shear heating is not significant during dynamic slip. Fault slip speeds during earthquake rupture are on the order of meters per second and for large earthquakes will last many seconds at hundreds of MPa normal stress (appropriate for seismogenic depths). Under these conditions significant shear heating should occur, resulting in dynamic weakening due to shear melting or pore fluid pressurization due to thermal expansion (Chapter 29 by Sibson). Consequently, conventional laboratory measurements of strength are unlikely to apply. Effects unrelated to shear heating but not considered in Eqs. (18) are also possible. Dynamic reduction of fault strength by normal stress reduction has been predicted on theoretical grounds (Weertman, 1980) and observed in numerical models (Ben-Zion and Andrews, 1998).

Many important unresolved issues in seismology are related to or determined by the strength during dynamic slip. If

dynamic weakening occurs, dynamic stress drops can be much larger than static drops (Brune, 1970, 1976), and rupture is more likely to propagate as a self-healing slip pulse (Heaton, 1990; Cochard and Madariaga, 1994; Perin *et al.*, 1995; Beeler and Tullis, 1996) rather than as a conventional crack-like rupture (Zheng and Rice, 1998; Chapter 12 by Madariaga and Olsen). If the dynamic stress drop exceeds the static stress drop, larger ratios between the radiated energy and the seismic moment are expected for larger earthquakes than for small events (Abercrombie, 1995).

Stress heterogeneity in the fault zone also depends on dynamic fault strength. Geometrical effects (roughness of the fault surface) and nonuniform material properties lead to stress heterogeneity, but heterogeneity may also result during dynamic rupture propagation and arrest (e.g., Cochard and Madariaga, 1994). Such stress roughening during dynamic propagation is common in numerical models, particularly discrete representations of rupture such as Burridge–Knopoff models, and is associated with simulated earthquake populations which obey the power law Gutenberg–Richter relation between occurrence and event size. Aspects of the association of rough spatial stress distribution and Gutenberg–Richter event populations are summarized by Rice (1993) where it is argued that discrete models are not satisfactory representations of a continuum, and continuum models of dynamic rupture propagation using laboratory values for fault strength generally do not result in a rough residual stress and Gutenberg–Richter populations. The latter is true in particular if Eq. (18) are used (Rice, 1993; Rice and Ben-Zion, 1996). However, more extreme rate dependence of fault strength, such as would result from dynamic weakening (e.g., Zheng and Rice, 1998), does lead to stress roughening (N. Lapusta and J.R. Rice, unpublished data). Thus many open questions and unresolved debates might be resolved by appropriate laboratory determinations of dynamic fault strength.

6.1 Frictional Strength at High Sliding Rates

Measures of fault strength during dynamic rupture events (Okubo and Dieterich, 1986) which have average sliding velocities on the order 0.1 m sec^{-1} are consistent with frictional strength, i.e., the predictions of Eqs. (18) during stick-slip. However, the implied temperature change in those experiments as estimated from

$$\Delta T = \frac{\tau \Delta \delta}{w \rho c} \quad (29)$$

where w is the fault zone width, ρ is density and c is the specific heat (Lachenbruch, 1980) is not sufficient to induce weakening due to melting (there is no pore fluid) (Lockner and Okubo, 1983). This is primarily due to the small total slip $\Delta \delta$ (80–100 μm) and low normal stress in the experiments. Measurements of fault strength at constant but lower sliding velocity (up to 3.2 mm sec^{-1}), dry, and at much higher cumulative

displacement (500 mm), lead to strengths that are also generally consistent with Eq. (18) (Blanpied *et al.*, 1998b) (see also Yoshioka, 1985; Mair and Marone, 1999). However, in the experiments of Blanpied *et al.* (1998b), sliding at the highest velocity and the highest normal stress (25 MPa induced anomalous weakening with displacement. This weakening did not occur at the lower normal stress (10 MPa).

6.2 Dynamic Weakening (New and Provisional Results)

Recently, dynamic weakening has been measured experimentally. The results, summarized in this section, fall into the two classes mentioned at the outset of this section: dynamic weakening due to reduction of normal stress and weakening due to shear heating. However, to date, none of the experimental measurements of weakening are definitive and some of the results summarized in this section are unconfirmed. In some cases the results or their relevance to natural faults are uncertain.

Dynamic weakening due to normal stress reduction was first observed in this context during stick-slip sliding between surfaces of foam rubber (Brune *et al.*, 1993; Anooshehpour and Brune, 1994). The observations consist of particle trajectories as the rupture passed and indicate opening displacement during the passage of a dislocation-like slip pulse (Fig. 22a). Because the frictional properties of foam rubber are quite unlike rocks [e.g., $1.0 < \mu < 3.7$ (Brune and Anooshehpour, 1997)], the experiments which are conducted under very low normal stress ($0.9\text{--}7 \times 10^{-6} \text{ MPa}$) are difficult to scale to the Earth. Some indication of the extreme differences between stick slip of foam rubber and rock is that for foam rubber, stick slip only occurs at the lowest normal stress; increasing normal stress leads to stable sliding (Anooshehpour and Brune, 1994), in contrast to the observation for friction of rocks and other brittle materials where increased normal stress promotes instability [e.g., Eq. (17) or (19) (Walsh, 1971; Goodman and Sundaram, 1978; Dieterich, 1979)]. These criticisms do not negate the applicability of the foam rubber observations to seismic failure, but they do emphasize fundamental differences between the behavior of foam rubber and rocks at laboratory conditions. The association of true opening displacements and stick slip for foam rubber suggest that this mechanism of instability is encouraged by low normal stress.

Dynamically reduced normal stress has been measured or inferred for materials other than foam rubber (Tostoi, 1967; Bodin *et al.*, 1998; Brown, 1998), suggesting that the foam rubber may be a valid laboratory rock analogue. Significantly, observations relevant to dynamic reduction of normal stress have been made for rock by Brown (1998). Heat generation during stick-slip between Westerly granite surfaces occurs at a lower rate than during stable sliding (Fig. 22b). Brown also found the mean stress during stick slip to be lower than during stable sliding. Assuming that the mean frictional strength is the same for both stick slip and stable sliding, the observations

FIGURE 22 Dynamic weakening: normal stress effects. (a) Shear (S) and normal (N) displacements in foam rubber during a stick-slip event. (b) Heat generation during stick-slip versus stable sliding on unconfined, initially bare Westerly granite.

can be interpreted to be due to dynamic reduction in normal stress during stress drop.

Dynamic weakening has been reported due to shear heating in unconfined experiments at modest normal stress on gabbro (Tsutsumi and Shimamoto, 1997). Fault strength expressed as frictional resistance drops to the range $\mu = 0.4$ – 0.5 (Fig. 23) [$\sigma_n = 1.5$ MPa (Tsutsumi and Shimamoto, 1997)] at sliding velocities of 0.43 – 1.3 m sec⁻¹ during melting and at sliding velocities of 100 – 550 mm sec⁻¹ when melting is not observed. The effect in the shear melting experiments is not as dramatic as one might expect, perhaps because of high melt viscosity

FIGURE 23 Dynamic weakening due to shearing: strength plotted as a function of sliding velocity for unconfined gabbro at 1.5 MPa normal.

(Tsutsumi and Shimamoto, 1997), but more likely because the melt is unconfined and is extruded by centrifugal force at these high sliding velocities (experiments are done in a rotary shear geometry). Unconfined experiments conducted by Spray (1987, 1988) on metadolerite and amphibolite at $\sigma_n = 50$ MPa and mean sliding velocity of 0.24 m sec⁻¹ show no evidence of weakening though accuracy of the stress determination is poor.

Preliminary results on confined and unconfined surfaces of quartzite and granite at slip rates of only 3.2 mm sec⁻¹, normal stresses of 28 – 112 MPa, and slip displacements of 0.2 – 10 m, show that friction can dramatically decrease with slip. In some cases the friction drops below 0.3 , or roughly 30% of the value typically found in quartz friction experiments (D. Goldsby and T. Tullis, unpublished data). Calculations of both average surface temperature and local temperatures at contacting asperities (i.e., so-called “flash temperatures”) predict maximum temperatures of 100 – 600°C . In most cases, the dramatic frictional weakening occurs at estimated temperatures below 300°C . Hence, the weakening is difficult to reconcile with melting, either of the entire fault surface or at asperities. It appears, however, that both temperature and displacement are important variables affecting the shear resistance. High temperature triaxial quartzite experiments (restricted to a few millimeter displacements), at temperatures that span the range of frictionally generated temperatures in the Goldsby and Tullis experiments, yield typical values of the friction coefficient of 0.6 – 0.8 (Stesky *et al.*, 1974). Large displacement experiments (sheared to several meters) at velocities greater than 100 $\mu\text{m sec}^{-1}$, which generate much less heat than the 3.2 mm sec⁻¹ experiments over similar displacements, also result in typical frictional strength. A possible explanation is that the low friction coefficient results from shear heating of profoundly altered, likely amorphous, material along the fault.

7. Deep Earthquakes

Seismicity can extend well below the conventional brittle ductile transition (Fig. 10). This is particularly true in subduction zones where earthquakes occur to depths around 600 km (see Fig. 10c inset). Following Frohlich (1989) we refer to intermediate focus events as those occurring in the depth range 70–300 km and deep focus events as those occurring at depths greater than 300 km. If conventional fracture and frictional instability were the only mechanisms of earthquake failure then seismicity would not exist below depths where the resolved shear stress on a fault is equivalent to 2000 MPa (e.g., Raleigh, 1967), the maximum flow stress above which all rocks and minerals deform by stable creep. For example, in a thrust faulting environment, assuming that σ_3 is fixed at overburden, pore pressure is hydrostatic and $\mu = 0.7$ (ignoring cohesion); failure of optimally oriented faults at this shear stress would occur at about 75 km depth. Obviously, the depth distribution of natural seismicity which indicates significant seismicity at 600 km cannot be interpreted in this simple manner. A number of mechanisms have been proposed to explain deep earthquakes. In this summary we focus on those that are supported by laboratory experiments. Not considered, for example, are models such as those based on a thermal instability (Griggs and Baker, 1969; Hobbs and Ord, 1988) which currently lack experimental support.

Laboratory observations indicate that earthquakes could accompany phase changes in the otherwise ductile portion of the crust. For example, brittle fracture occurs following reduction of the failure stress due to increased pore fluid pressure from a dehydration reaction. This dehydration embrittlement mechanism can explain intermediate events if hydrated minerals are present. Failure can also be triggered by heat from a phase transformation as well as differential stress around inclusions resulting from a phase transformation. Transformation-induced faulting provides a likely mechanism for deep focus events. Radiated stress and inelastic shear displacements result from other phase transformations such as melting (Griggs and Handin, 1960) and amorphization (Meade and Jeanloz, 1991).

7.1 Intermediate Focus Events

The explanation of intermediate focus earthquakes follows directly from the effective pressure law $\sigma_{n,eff} = \sigma_n - p$, Eq. (7), which was previously discussed in the context of Eq. (1a). Failure strength in excess of cohesion can be reduced to arbitrarily low levels if the pore pressure is high. At intermediate focal depths, where the high overburden stress and high temperature lead to time-dependent creep and recrystallization, porosity and pore connectivity are significantly reduced (Lockner and Evans, 1995). Under these conditions, water, provided by dehydration reactions, can exist at near lithostatic

FIGURE 24 Dehydration weakening. Strength of serpentinite deformed at a strain rate of $7 \times 10^{-4} \text{ sec}^{-1}$, and confining pressures of 100, 350, and 500 MPa as a function of temperature.

pressures and shear fracturing can occur at very low shear stress (Hubbert and Rubey, 1959). Experimental confirmation of this theory was made by Raleigh and Paterson (1965) who observed brittle failure of serpentinite at its dehydration temperature, but ductile behavior at lower temperatures (Fig. 24). Acoustic emissions were detected during dehydration at pressures up to 9 GPa (Meade and Jeanloz, 1991) confirming that this mechanism is capable of the rapid unstable deformation associated with earthquakes.

There are four requirements for dehydration embrittlement to be a viable model for intermediate events:

1. The brittle failure strength must be smaller than the ductile shear strength because the ductile shear strength would otherwise limit the stress available to drive failure.
2. The sliding frictional strength must be smaller than the failure strength so that a coseismic stress drop is possible. These first two requirements are met for serpentinite experiments (Raleigh and Paterson, 1965).
3. Faulting must occur under undrained conditions, since a loss of pore pressure would increase the shear resistance and stabilize the incipient rupture. At intermediate depths where porosity and permeability are extremely low, undrained conditions are expected to be the norm. In this case the stress drop during dehydration faulting is well described by a loss of cohesion.
4. Dilatancy must be suppressed or else the pore pressure will be reduced due to dilatancy hardening (Rice, 1975; Rudnicki and Chen, 1988).

Recent experimental observations of failure of serpentinite even at low confining pressure indicate that deformation is accommodated on shear microcracks that are aligned preferentially with the cleavage direction, as opposed to macroscopic shear fractures initiated from dilatant microcracks (Escartin *et al.*, 1997). Thus little or no dilatancy can be expected during deformation of serpentinite at high pressure. Application of the Hubbert and Rubey mechanism to explain intermediate focus events is limited to regions of the crust where dehydration is on-going and also by the constraint that the pore pressure not exceed the least principal stress. However, the conditions necessary for instability have not been rigorously determined for this mechanism.

7.2 Deep Focus Earthquakes

Failure of the crust in deep focus earthquakes occurs well below the depth where the frictional failure strength exceeds the flow strength of rock, and below temperature and pressure conditions of dehydration reactions. Deep focus events therefore require a mechanism that is different from shallow seismic failure in fundamental ways. Among the exotic mechanisms called upon to explain deep focus events is transformation induced faulting (Vaisnys and Pilbeam, 1976), where failure is associated with a phase transformation such as the pressure-driven olivine–spinel transformation. This mechanism is well documented in experiments, notably in water ice I to ice II where faulting is accompanied by release of radiated energy (Kirby *et al.*, 1991), a key requirement for any explanation of deep earthquakes. Transformational faulting also occurs in Mg_2GeO_4 which has the same structure as Si olivine (Fig. 25) (Burnley *et al.*, 1991) and, at temperatures, pressures, and mineralogy consistent with subduction zones, in $(\text{Mg,Fe})_2\text{SiO}_4$ (Green *et al.*, 1990). The key observations which distinguish this mechanism from conventional brittle failure are the presence of the transformed phase in the fault zone and in transformed lenses in fault parallel lineations, and the lack of precursory acoustic emissions which are associated with dilatancy during nucleation in conventional frictional failure. That the lenses of transformed material tend to be oriented with their long axis perpendicular to the stress field indicates that the transformation itself is controlled by the deviatoric stress. However, the exact mechanism and mechanics of transformational faulting are not well understood. Suggested mechanisms include the coalescence of transformed material into a shear zone (Kirby, 1987) or transformed material initiating a through-going shear fracture (Ringwood, 1972; McGarr, 1977). Similarly it is not entirely clear whether the weakness of the shear zone which leads to a stress drop in experiments is due to the fault being made of fine-grained transformed material with reduced shear (flow) strength or because of a loss of cohesion during the formation or propagation of the shear zone. Advances have been made in theory to accompany and explain the laboratory observations. Lui (1997) has determined

FIGURE 25 Transformation induced faulting in germanate Mg_2GeO_4 . (a) Stress versus natural strain. (b) Summary of deformation experiments on olivine–spinel phase transformation at strain rates of 2×10^{-4} and $2 \times 10^{-5} \text{ sec}^{-1}$.

conditions necessary for formation of a transformed shear zone and the associated stress drop based on thermodynamic considerations and the kinetics of the phase transformation. However, the conditions necessary for rapid (seismic) failure have not been determined. Other phase transformations may lead to shear instabilities. Meade and Jeanloz (1991) report acoustic emissions and shear deformation associated with a crystal to glass transformation in serpentinite between 6 and 25 GPa. Other hydrated minerals may also amorphize in this manner.

Acknowledgments

We greatly appreciate the thoughtful reviews provided by J. Byerlee, C. Sammis, C. Scholz, R. Sibson, and W. Stuart. This work was supported in part by the National Earthquake Hazards Reduction Program.

State of Stress Within the Earth

Larry J. Ruff

University of Michigan, Ann Arbor, USA

1. Introduction

Stress makes geologic processes happen, and geologic processes make stress. Plate tectonics, earthquakes, volcanic eruptions, glacial rebound, landslides, tidal deformation, phase changes, fluid flow, rock folding, and crystallization are examples of processes that generate, modify, and consume stress within the Earth. Since stress is the continuum equivalent of force, it is expected that any mechanical process in the solid or fluid parts of the Earth must involve stress. Gravitational forces acting on and within the Earth are intimately connected to stress state, and earthquakes occur when the shear stress exceeds the failure level for the fault. Some classic results on the stress state of the Earth are valid today, yet stress remains as a topic of intense study across many disciplines in the Earth Sciences.

The central role of stress and the long history of stress studies make it impossible to reference all relevant works. Instead, I will reference several other review papers that contain extensive lists of references. Also, I cannot possibly give comprehensive discussions of all the problems and considerations for all methods and results. Instead, I will resort to simplified summaries and broad sweeping statements as much as possible, though always supported by references. In many instances, I will reference the special issue on a topic, rather than individual contributions. Many subjects and investigators have a long literature history, so I reference just one recent paper that gives the earlier citations. More emphasis will be given to some recent trends in stress studies.

This review of stress first discusses the basic definition of stress and a simplified view of rock strength. The stress state can be divided into two parts: pressure and shear stress. There are no significant controversies today surrounding the state of pressure within the Earth, so that section is relatively short. Then we turn to shear stresses within the Earth. Although shear stress is small compared to pressure in most of the Earth, shear stress is the subject of most interest today. Any discussion or study of shear stress includes constraints from several different methods. This review orders the methods from the

most reliable to the more controversial methods and topics, such as earthquake stress drops, plate boundary heat flow, and fault pore pressure. If earthquake hazards are the primary concern, then the most important aspect of stress state is the difference between shear stress and failure stress levels. Although this topic has a long history in seismology, it has attracted several recent studies from both a theoretical view and observations of induced seismicity and earthquake triggering.

The conclusions of this review echo those of previous reviews: support of mountains requires shear stresses of at least 75 MPa somewhere in the lithosphere; stresses associated with plate tectonics are about 10 MPa at plate boundaries, and reach higher values in the strong portions of plate interiors; and although stresses vary wildly in both direction and magnitude in the upper crust at short length scales, there are coherent large-scale trends of stress direction that can be connected to global-scale tectonics. On the other hand, there are significant questions related to low stresses on plate boundaries and major faults. Pore fluid pressure is now a popular mechanism to explain weak faults, but there are still some unresolved contentious issues. Also, the related notions of a uniformly critically stressed crust and earthquake triggering forces us to take a broader view of earthquake hazards.

1.1 Aspects of the Stress Tensor

Stress is a well-defined physical quantity throughout the interior of any fluid or solid material. Basic rules of force balance on a small material element lead to the construction of the stress tensor, which can be viewed as three mutually perpendicular force dipoles acting on the faces of the material element (Fung, 1965; Aki and Richards, 1980). These three dipoles are commonly referred to as the principal stresses, and the units of stress are force per unit area ($1 \text{ Pa} = 1 \text{ N m}^{-2}$). The stress tensor accounts for the orientation and strength of the force dipoles, and can vary with time for a given material element or location. Tides cause global variations at a time scale of a day. Earthquakes cause variations at shorter time scales throughout the

Earth due to seismic waves, and at longer time scales near the fault due to the static stress changes. Other geologic processes, such as ice or sediment loading, cause variations at a variety of time scales. Each element inside the Earth is subjected to all these influences.

If all scientists always referred to stress tensor components in the same global coordinate system, then we could avoid most of the confusion and terminology difficulties with stress. But it is more useful to describe stress with respect to local geometry; for example, the trend of a local fault. Furthermore, many studies focus on shear stress size, regardless of orientation. Thus, some terminology inconsistencies are bound to appear. Here, I provide just the notation used in this review.

The most important division of the stress state is into the pressure and shear stresses; this corresponds to splitting the stress tensor into the isotropic and deviatoric parts. The isotropic part is well defined as the “pressure,” but unfortunately there is some confusion due to the sign convention. Most formal treatments of stress define a tensional force dipole as positive (e.g., Fung, 1965), which leads to the compressive pressure inside the Earth as being negative pressure. However, there is a long tradition in the Earth Sciences that refers to compressive pressure as positive pressure. Since this overview does not need to follow rigorous derivation of equations, I adopt the common geologic usage and refer to compressional pressure as positive. As shown in Figure 1a, pressure is formally defined as one-third the trace of the stress tensor; or in other words, pressure is the average value of the principal stresses. The “sign” of shear stresses is more difficult than for pressure. Hence, it is common practice in the Earth Sciences to give a description for the shear stress geometry in terms of complete geographic faulting notation: e.g., “shear stress of 10^5 Pa in the sense of right-lateral shear along a plane of N45°W strike and 45° dip to the NE.” Figure 1a illustrates how a stress tensor for a single force dipole is decomposed into the isotropic part and deviatoric part. Sometimes the deviatoric part is further decomposed into two “pure shear double couples.”

A common description of the stress state is to quote the “normal” and “shear” stresses with respect to a particular plane slicing through the material. In this context, “normal” stress refers to the force component perpendicular to the plane, whereas “shear” stress refers to the force component acting parallel to the plane. For many applications, the plane is a preexisting fault plane. This view is most useful when testing the stress state against some frictional failure criterion. In the matrix representation of stress, “normal” and “shear” stresses are the diagonal and off-diagonal components of the stress tensor after it has been rotated to a new coordinate system that coincides with the plane orientation. Mohr’s circles provide a clever geometric visualization of this view of the stress state. The Mohr’s circle in Figure 1b also helps to illustrate some of the confusion over shear stress. Since many scientists and engineers use Mohr’s circles for stress analysis, it is natural to

FIGURE 1 Stress tensor for a single vertical force dipole (σ_{zz}) represented by isotropic and deviatoric components (a) or by Mohr’s circle (b).

think that shear stress should be defined with respect to a particular plane. As a plane is rotated from an initial orientation that is normal to the maximum principal stress, then shear stress along the plane increases from its initial value of zero.

In the matrix representation, shear stress would be the off-diagonal components of a stress tensor that is rotated from the initial diagonalized form to some arbitrary coordinate system. In the context of the matrix representation, the “natural” coordinate system orientation for any stress tensor is the one that diagonalizes the stress tensor to find the three force dipoles. In this “natural” coordinate orientation, shear stresses are represented by differences in the size of the three principal stresses. Thus, a good invariant, i.e., independent of any particular planar orientations, measure for shear stress is the difference between the greatest and least sizes of the principal stresses; this quantity is commonly called the “stress difference,” and I will use this term (it is also referred to as the “differential stress” in some places). But the Mohr’s circle in Figure 1b shows us that maximum value of the shear stress resolved onto a single plane is half the stress difference. For the example in Figure 1 where two normal stresses are the same, we can achieve this maximum shear stress value not just on one plane, but on all planes inclined at 45° to the vertical axis. Again, I shall adopt the common geologic usage that refers to shear stress as resolved on a plane of a particular orientation. When I use “shear stress” with no further qualification, it will be the maximum shear stress obtained from a Mohr’s circle plot; that is, half the value of the “stress

difference.” Of course, shear stress values quoted in many of the references might follow other conventions.

How large is a “small material element?” If the stress tensor is homogenous across a large volume, then the entire volume can be considered a “small element.” For example, planetary scale calculations might assume that large blocks of the Earth’s lithosphere have a uniform stress, then the entire block can be thought of as a single material element with a single stress state. On the other hand, one rock from the middle of this lithospheric block might display significant variations in both orientation and size of stress (see Zoback, 1992, for introduction to special issue). Thus, we must realize that the stress tensor at any one site is the superposition of contributions from different processes that range from global-scale tectonics to microscopic cracks.

1.2 Rock and Fault Strength

Many of the constraints on stress state in the Earth are based on the physical properties of rocks and faults. Mantle and crustal rocks are capable of sustaining shear stresses either from a short-term elastic response, or a fluid flow response for longer times. Laboratory experiments on rocks have established the overall broad constraints on the maximum strength of mantle and crustal rocks (see chapters in Jaeger and Cook, 1979; Scholz, 1990). Here tensional and compressional strength are first briefly discussed followed by shear strength.

Rocks and other materials are weakest for tensional stresses. Tensional failure may be important for some phenomena close to the Earth’s surface, and might be part of the microscopic mechanisms of shear failure at depth. Rocks become stronger as isotropic compression increases, unless the pressure becomes so large that they undergo a solid-to-solid “phase change” that increases density. These high-pressure phase changes may be regarded as volumetric failure, though in most cases phase changes occur slowly. Phase changes are known to occur in many crustal rocks as they subside or emerge. Various candidate mantle rock compositions undergo phase changes at the depths of the observed upper-mantle seismic discontinuities (see Chapter 51 by Lay). If rocks are advected through these phase-change boundaries, either in subduction zones or elsewhere, then phase changes are an active process of the present-day earth. Even if phase changes are slow, they might cause earthquakes due to the induced shear stresses. In addition, a current popular explanation for deep Wadati–Benioff zone earthquakes makes use of kinetically delayed phase changes in the subducting slab (Kirby *et al.*, 1996; Green and Houston, 1995).

The shear strength of rocks is directly related to earthquakes, mantle flow, and support of topography and bathymetry. In the laboratory, rock samples can be selected that have no through-going fractures. These experiments give us the upper bound on bulk rock strength (see Chapter 32 by

Lockner and Beeler). To simplify the results, divide rock behavior into two regimes that depend largely on homologous temperature: cold rocks are brittle, hot rocks are ductile. In the brittle regime, increasing shear stress deforms the rock elastically until brittle failure begins and eventually the rock breaks. Failure stress is a small fraction of the shear modulus; a typical shear stress value at failure for uniaxial experiment on crustal rocks is 100–150 MPa (Jaeger and Cook, 1979). Failure stress increases with pressure, but in the Earth, the temperature increase eventually places the rock in the ductile regime. In the ductile regime of high temperatures and slow strain rates, the rock acts like a fluid with high viscosity. A ductile rock still behaves elastically to transient perturbations of stress. For example, deep mantle rocks that are flowing as part of mantle convection also transmit seismic waves, and if some sharp stress transient were to occur such as stress loading due to a nearby earthquake, they might show brittle failure. This complex behavior of rocks makes it difficult to assign a single shear stress to rocks as their ultimate strength, but the rock strength envelopes (Goetze and Evans, 1979; Brace and Kohlstedt, 1980) usually show peak shear strength values of about 100–150 MPa at the brittle–ductile transition depth of 15 km or so in continental crust. Other studies (e.g., Molnar, 1992) argue that the peak ductile shear strength of 100 MPa is reached just below the Moho.

Other laboratory experiments are performed on fractured rocks to test the frictional sliding properties on various contact surfaces. In these experiments, a normal stress is applied to the crack surface, then the shear stress is increased until slippage occurs. Over a wide variety of conditions, it is found that the ratio of shear to normal stress is constant; this ratio is the coefficient of friction. For common crustal rocks, “Byerlee’s Law” states that the coefficient of friction is about 0.6–1.0 (Byerlee, 1978). If the lithosphere has faults of all orientations, then these results give the upper bound for shear strength of the lithosphere, where the normal stress is approximately the same as the pressure. Byerlee’s Law is added to the Mohr’s circle plot in Figure 1b. This diagram then shows the range of fault plane orientations that are stable in the sense that shear stress is less than the value required to overcome static friction. One major complication for frictional sliding is that normal stress may be reduced by fluid pore pressure to the “effective normal stress.” Pore pressure reduces all principal stresses by the same amount, essentially shifting the Mohr’s circle in Figure 1b to the left. Since Byerlee’s Law remains the same, this shift reduces the shear stress level required for fault slip. This issue is returned to later in the discussion of weak plate boundaries.

If the pore pressure is greater than the least principal stress, then the left-ward shift of the Mohr’s circle places this least principal stress into the tensional stress regime which causes “hydrofractures.” There are many technological applications of hydrofracturing in boreholes and it also provides many of the deep direct stress measurements (see Chapter 34 by

Zoback and Zoback). One consequence of hydrofracturing is that fluids flow into the open tensional cracks and pore pressure consequently decreases, unless the crack stops growing and there is a large reservoir of high-pressure fluid. In the discussions of water and weak plate boundaries, we will see that avoidance of hydrofracturing is one of the key constraints on models.

2. Pressure within the Earth

Isotropic stress state within the Earth is based on calculations of the gravitational loading. It can be measured by direct techniques, but estimates based on rock loading are more reliable. The vertical force dipole, σ_{zz} , at a depth of H is the integral of the product of gravitational acceleration (g) and density (ρ) from the surface down to depth H . The Earth's density structure is nearly spheroidally symmetric. The largest lateral variations are near the Earth's surface, and there are small perturbations throughout the mantle. Although the gravitational acceleration inside the Earth depends on the density model, gravitational acceleration through the mantle must be nearly constant for any reasonable earth model that matches the basic constraints of radius, mass, moment of inertia for the Earth, and the core-mantle boundary radius. This convenient coincidence for our planet makes it particularly easy to calculate buoyancy effects anywhere in the crust and mantle. Thus, there is little error in the value of " g ", and the subsequent variations in σ_{zz} through the mantle are even smaller. Pressure estimates at the core-mantle boundary have changed from Bullen's Model A (Bullen, 1947) estimate of 137. GPa to the PREM value of 135.7 GPa (Dziewonski and Anderson, 1981). Pressure in the core smoothly increases to a value of 363.8 GPa at the Earth's center. Unless someone discovers major flaws in the constraints or methodology of earth model construction, deep Earth pressure estimates will change by less than 1%. Thus, current interest in pressure is focused on the fluid Earth and the uppermost crust.

2.1 Fluid Pressure Variations in the Earth

The ocean and atmosphere apply pressure to the Earth's surface. Since the lateral density variations and dynamic pressure effects of the atmosphere and oceans are small (i.e., less than 10%), fluid pressure is accurately predicted from either elevation or bathymetry. Atmospheric pressure at sea level is quite close to 10^5 Pa or 1 bar (standard pressure is 1.013 bar). This same pressure can be achieved by the gravitational load of a 10 m tall column of water, or a 4 m rock column. Thus, for most purposes, we can ignore the atmosphere and refer to the Earth's surface as a stress-free boundary. There are a few phenomena where atmospheric pressure must be included, for example, seismic noise generation by weather, and Chandler wobble excitation. Although the dynamic pressure perturbations caused

by storms is small, Diakonov *et al.* (1990) review some evidence of induced microseismicity.

At a typical ocean basin depth of about 5 km, the water column pressure is about 50 MPa. This pressure is equivalent to a rock column height of 2 km. Some geologic phase relations change over this pressure interval, thus water overburden pressure is significant for some shallow processes. Dynamic variations in water pressure are due to tides, waves, and currents. These dynamic perturbations are small and can be ignored for most solid-earth applications. Some exceptions are the "microseism" noise which is due to ocean wave pressure fluctuations (see review by Haubrich and McCamy, 1969; and special issue, Hjortenberget and Nikolaev, 1990), and coastal gravity and geodetic measurements that are sensitive to tilting caused by tidal loading of continental shelves. It is even possible that ocean tide loading triggers volcanic eruptions (see Chapter 25 by McNutt) and earthquakes (Tsuruoka *et al.*, 1995).

One other fluid region of the Earth is the outer core. Pressure is accurately predicted by global earth models. Lateral pressure variations in the outer core must be very small, but similarly to the ocean and atmosphere, large fluid motions can occur with tiny pressure variations.

2.2 Pressure Variation in the Solid Earth

The largest fractional variations in σ_{zz} within the Earth are in the uppermost crust. Small rock bodies of unusual density can cause small anomalies, but the strongest variations will be caused by open fractures, or even caves. A cave's free surface requires that the normal stress is zero (or to be more precise, normal stress is 1 bar). Since the rock above the cave must still be supported, σ_{zz} is larger on either side of the cave, whereas the tangential stresses at the top and bottom of the cave can be tensional. Any open crack causes a strong perturbation to the stress field, which decreases away from the crack. At distances that are large compared to the crack size, the stress field is the same as that for no crack. There is a limit to how deep a cave can occur in the Earth due to rock weakness. If a cave generates tensional stresses at top and bottom, the rock will fail with just a modest amount of rock overburden. At deeper depths, the shear failure strength of rocks will be exceeded and the hole will fill with rock fragments. At lower crustal and mantle depths, plastic deformation can eventually close all open cracks. Many boreholes are drilled to depths of a few kilometers, but they are filled with a dense fluid to provide pressure support for the surrounding rock. For deep mines, however, the rock walls are at surface pressure, and these large values of stress difference can cause shear failure (Jaeger and Cook, 1979). In conclusion, any open cracks in the upper crust will have localized large stress perturbations, though this effect can be mitigated with high pressure fluids that fill the cracks.

The maximum stress difference may reach 100 MPa or more in the upper crust, but higher temperatures in the lower crust

cause the shear strength of rocks to decrease. Even if rocks could withstand shear stresses of 100 MPa all the way to the core–mantle boundary, this shear stress level fades to a minor perturbation compared to the pressure, which continues to increase to over 100 GPa. Thus, at the bottom of the mantle, the maximum shear stress is less than a factor of one thousand smaller than the isotropic part of the stress tensor. The two horizontal principal stresses are approximately equal to σ_{zz} throughout the mantle and so the pressure is also equal to σ_{zz} .

Subducting slabs may perturb the pressure state of the mantle. Rock is subducted down to a depth of at least 670 km, and it is likely that this rock undergoes phase changes. It is possible for the interior of active phase-change inclusions to be at a different pressure from the surrounding rock, but the shear stress induced in the surrounding rock relaxes to reload the inclusion back to the ambient pressure. Deep earthquakes were once thought to be part of this “relaxation” process (for reviews and recent ideas about deep earthquakes, see Frohlich, 1989; Green and Houston, 1995; Kirby *et al.*, 1996).

In conclusion, the stress tensor is nearly isotropic throughout most of the Earth. Furthermore, there are reliable quantitative estimates of this pressure. However, it is the shear stress, those small deviations away from the isotropic stress state, that is the main interest of geologists and geophysicists. Part of this interest stems from the fact that shear stress is “unknown,” but it is also due to the fact that shear stress is fundamental to many interesting geologic processes such as plate tectonics, mountain building, earthquakes, volcanic eruptions, and landslides.

3. Introduction to Shear Stress within the Earth

In general, we want to know both the orientation and size of shear stresses. As summarized in the World Stress Map Project (introduction by Zoback, 1992), there are many more reliable indicators of orientation than of size. In the present review, the brief discussion of orientation is in the “Direct Measurements” section; the related review (Chapter 34 by Zoback and Zoback) contains more information on shear stress directions. The sections below emphasize shear stress size.

Many different methods place constraints on shear stress. This review presents the methods in order from the most reliable to the most controversial. Gravitational loading places the best constraints on minimum shear stress size. This method also provides robust estimates of the minimum shear stresses associated with plate tectonics. Direct measurements give us the somewhat surprising conclusion that shear stresses may be near their maximum allowed value nearly everywhere in plate interiors. We end with the interconnected topics of earthquake stress drops, heat flow, plate boundary stresses, and pore pressure. There is a long-standing debate in Earth Sciences between proponents of “low” (10 MPa) and “high”

(>50 MPa) shear stresses. Earlier review papers (e.g., Kanamori, 1980; Hickman, 1991) have offered a compromise of high stresses beneath mountains and low stresses acting along plate boundaries. It seems that this compromise view can accommodate most of the quantitative results acquired in the last two decades. Indeed, much of the debate has now shifted to exactly how plate boundaries are able to operate at low shear stress levels.

4. Gravitational Loading

Gravity produces most of the large stresses within the Earth, and these stresses can be reliably calculated. The best constraints on minimum shear stress size are based on gravitational loading. Lateral variations in density, topography, and bathymetry are responsible for most of the shear stress within the Earth. One of the first and still most powerful statements about stress state is the classic Jeffreys argument about support of mountains. This argument leads to all modern research in mantle density anomalies, geoid, and plate tectonic stresses.

4.1 Classic Jeffreys Argument for Shear Stress

The essence of the Jeffreys argument is that pressure at the bottom of a load sitting on the Earth causes shear stresses somewhere that are about one-sixth to one-quarter the size of the load pressure (Jeffreys, 1970; see McNutt, 1980, for discussion of the Jeffreys argument). Figure 2a shows the trivial case where the stress difference in the rock sample at the base of the cliff is $(\rho g H)$, where g is gravitational acceleration, ρ is rock density, and H is height of rock column. For this rock sample, the shear stress will be $(\rho g H/2)$. With a plateau height of 5 km, this rock sample would have a shear stress of about 63 MPa (or 630 bars). Shear stress in the underlying elastic half-space is 20 MPa along the circular arc in Figure 2a.

A more realistic profile for a mountain chain is the triangular cross-section shown in Figure 2b, where the σ_{zz} loading at the center is $(\rho g H)$. Jeffreys showed that if you apply this load to an elastic half-space, the peak shear stress is $(0.512)(\rho g H)/2$ at a depth that is about one-quarter of the mountain width. Hence, peak mountain height determines the

FIGURE 2 Illustration of stresses induced by gravitational loads. In (a), a plateau with height H is placed on the Earth. A triangle-shaped mountain is placed on the elastic half-space in (b).

peak shear stress, regardless of the slope. The analysis becomes more complex if one allows for relaxation and modification of the elastic stress field. Clearly, use of fluid rheology below a certain depth concentrates and increases the shear stresses in the upper layer. Jeffreys discusses various methods to redistribute stress, but notes that reduction of stress in one place necessarily increases it elsewhere. The reduction in peak shear stress from the elastic solution is quite small. One extreme, yet simple, illustration of the efficacy of the Jeffreys argument is the Stokes problem of a high density sphere sinking through a viscous fluid (Turcotte and Schubert, 1982). The gravitational load for a vertical column through the sphere's center is $(\Delta\rho g 2R)$, where $\Delta\rho$ is the density anomaly of the sphere with radius R . The peak shear stress in the fluid flowing around the sphere is $(1/6)(\Delta\rho g 2R)$ (i.e., one-sixth of the maximum load pressure) and is independent of the viscosity and flow velocity. Hence, although the rheology governs the deformation and details of stress distribution, it can not reduce the peak shear stress from the Jeffreys value. To quote from Jeffreys's (1970): "As a general guide it is safe to say that a variation of surface load with range $(\rho g H)$ implies a stress difference of about $(1/3)(\rho g H)$ to $(1/2)(\rho g H)$ somewhere."

To look at mountains from a broader perspective, large mountain chains are isostatically compensated at fairly shallow depth (100 km or less), and this serves to increase shear stress. Jeffreys went on to show that there must be shear stresses of at least 75 MPa beneath the Himalayas, and about half that level beneath other mountains belts such as the Alps, Andes, and the Rockies.

Any departure from spheroidal symmetry is associated with shear stresses. Lateral density anomalies could be calculated theoretically, such as the density variations from a mantle convection calculation, or they might be the results of gravity and geoid anomaly inversion. Variations in the Earth's surface and other boundaries are efficient "generators" of gravitational loads due to density contrasts across boundaries. There is more uncertainty in the stress estimates based on buried loads as compared to loads that we can "see," such as mountains, trenches, and ridges.

An active area of research has been to combine geoid anomalies with other constraints on internal heterogeneity such as seismic tomography (Bai *et al.*, 1992), or the history of subducted slabs (Lithgow-Bertelloni and Richards, 1998) to localize the density anomalies. Once this is done, the shear stresses required to support density anomalies and boundary variations can be calculated. Of course, Jeffreys (1970) already estimated the minimum shear stress level in the mantle required to support early estimates of the long-wavelength geoid anomalies; his stress estimate was about 10 MPa. Modern studies can increase that minimum value if they can better localize the gravitational loads responsible for the geoid anomalies.

One important advance has been the determination of lithosphere thickness that can support elastic shear stresses over geologic time. The advent of digital data sets for topography,

gravity, and numerical methods has allowed more accurate description. Oceanic lithosphere provides the best place to perform these studies (see review by McNutt, 1986). Most recent investigations have converged on a consensus view of elastic thicknesses [but see McKenzie and Fairhead (1997) for a contrary view, especially for the elastic thickness of continents]. For the future, geodetic strain rate constraints combined with gravity data promise to provide better rheological models and hence more detailed lithosphere shear stress estimates.

4.2 Stresses that Drive the Plates

Plate tectonics is the most important Earth Sciences paradigm shift in the 20th century. Although plate tectonics is a kinematic description, there has always been a keen interest in the stresses that drive plate tectonics. Most people now agree that mantle thermal convection is the underlying mechanism for plate tectonics, and that the oceanic lithosphere acts like the upper thermal boundary layer on top of this system. In addition, chemical differentiation and phase changes add buoyancy forces, though these are more difficult to estimate. A complete comprehensive simulation of mantle convection in the "real" earth with all buoyancy sources and proper rheology would produce the stress field that drives the plates. This comprehensive simulation has not yet been achieved. But we do not need to know the details of mantle convection to calculate the minimum level of associated shear stresses. Thermal convection produces regions of positive and negative buoyancy that "drive" the system. Hence, if we can see the buoyancy source, a Jeffreys-type calculation gives the minimum shear stress.

Now that we know where to look, we can "see" part of the plate tectonic load by observing the difference between young and old oceanic lithosphere. This is shown in Figure 3, where the two columns show the ridge crest and old oceanic lithosphere. It is easy to calculate the extra load at the ridge by replacing water with hot rock. It gives a loading stress of about 60 MPa. If we then simply apply the Jeffreys rule that minimum peak shear stress should be about $(1/6)\rho g H$, then we

FIGURE 3 Ridge push and plate force balance. A lower bound on peak shear stress associated with plate tectonics is based on the gravitational load of the ridge relative to old oceanic lithosphere (a). The requirement of zero net torque for a tectonic plate connects ridge push to other plate boundary forces (b).

obtain 10 MPa for the minimum shear stress associated with plate tectonics. With more sophisticated arguments, McKenzie and Jarvis (1980) estimated that plate boundary shear stress falls in the range of 10–50 MPa. Some early models of subduction that included the observational constraints of topography and gravity found that boundary shear stress must be less than 70 MPa (Sleep, 1975), with a typical value of 30 MPa. More recent estimates based on much more advanced models find that mantle and plate boundary stresses are “low” (for references, see Bai *et al.*, 1992; Richardson, 1992; Bird, 1998), less than 50 MPa.

4.2.1 Ridge Push and Slab Pull

One of the more popular uses of the ridge loading stress is to turn it into the horizontally directed ridge force. The basic procedure is shown in Figure 3a (see details and references in Artyushkov, 1973). The pressure at a depth of 100 km or so is the same below a ridge and old lithosphere (see Stein and Stein, 1992, for recent model of oceanic lithosphere). Assume a simple stress state of pure isotropic stress within each column so that horizontal stress equals σ_{zz} . Then the horizontal stress at a ridge is larger, but the pressure difference decays to zero at the lithosphere base as required by isostatic equilibrium. If a membrane were placed between these two columns, the ridge column would be pushing on it with the pressure difference as a function of depth. The integrated effect of this push is basically given by the product of the maximum pressure difference and the thickness of the lithosphere, divided by two. In detail, there is little extra push from the height difference between the ridge crest and ocean basin. This integral is then approximately ($g \Delta\rho \Delta H_{\text{ridge}} H_{\text{litho}}/2$), which equals $3 \times 10^{12} \text{ N m}^{-1}$ for H_{litho} of 100 km. Note that the units are ridge force per unit ridge length along strike. The number used for horizontal ridge push by several investigators (e.g., Hager and O’Connell, 1980; Richardson, 1992) is the same as above. More sophisticated global calculations, such as those in Richardson (1992), distribute this ridge push across the ocean basin, rather than just concentrate it at the ridge.

It is difficult to make reliable estimates for the gravitational load at subduction zones. Although we can easily “see” ridge push, much of the subduction zone load is buried and geoid interpretation is tricky. Of course, deep-sea trenches give some clue as to the buried mass excess in the subducted slab (Davies, 1983; Zhong and Gurnis, 1995) but we need more clues. The basic thermal contribution to slab buoyancy seems well established (e.g., Turcotte and Schubert, 1982), but the unknown plate boundary stresses affect thermal models (Peacock, 1996). Theoretical calculations of slab buoyancy keep changing as our notions about thermal structure, composition, phase changes, and – most recently – delayed phase changes in subducted slabs evolve (Ito and Sato, 1992). Nonetheless, slab pull forces for typical lithosphere structure are in the range of $4\text{--}10 \times 10^{12} \text{ N m}^{-1}$ (Spence, 1987; Whittaker *et al.*, 1992). Recent

estimates of slab buoyancy with kinetically delayed phase changes emphasize the “parachute” effect that limits subduction velocities (Marton *et al.*, 1999).

4.2.2 Global Force Balance and Plate Boundary Stresses

We now turn to more-specific global models of plate boundary and intraplate stresses. Since the influential paper of Forsythe and Uyeda (1975) on the global force balance on major plates, there have been many versions of global force balance calculations with the observed geometry of the Earth’s plates and plate boundary types. Once we assign forces to a certain type of plate boundary, the interconnected global plate system provides an opportunity to calculate the orientation and size of forces on other plate boundaries or areas (Fig. 3b). Forsythe and Uyeda (1975) concluded that “slab pull” force dominates “ridge push” by more than a factor of ten, but also that “slab pull” must be largely balanced by local resistive forces in the surrounding mantle and on the plate boundary. Forsythe and Uyeda (1975) also found that transform fault and subduction zone boundary forces were equal to or less than the ridge push force; hence plate boundary stress averaged over lithosphere thickness is about 30 MPa for transform boundaries and 15 MPa for subduction boundaries. Other global-scale calculations found a closer balance between ridge push and slab pull (e.g., Hager and O’Connell, 1980). Most force-balance models (e.g., Richardson *et al.*, 1979; Hager and O’Connell 1980; Richardson, 1992; Bird, 1998) find that plate boundary resistive stress averaged over the entire lithosphere thickness is approximately 10 MPa.

4.2.3 Global Tectonic Models with Intraplate Stress

The final step in these plate tectonic calculations is to use the buoyancy sources and boundary forces, assume some rheologic structure for the lithosphere, and then calculate plate interior stresses (depicted in Fig. 3b).

Model shear stresses within subducting slabs can be quite variable; typical values easily reach 100 MPa (Vassiliou and Hager, 1989; Wortel and Vlaar, 1988; Whittaker *et al.*, 1992). Outer-rise stresses were a focal point for the low versus high stress debate, but further modeling showed that the non-uniqueness in plate rheology imparts large uncertainties in the model stresses (see Hanks and Raleigh, 1980; Kanamori, 1980). Now the emphasis is on the contributions of bending and time-dependent stresses through the Earthquake cycle to the outer-rise stress state (see Dmowska *et al.*, 1988; Christensen and Ruff, 1988; Liu and McNally, 1993). Also, stress regime of the double seismic zone at intermediate depths continues to present a perplexing problem (Kawakatsu, 1986; Seno and Yamanaka, 1996).

The last topic is the most complex and is an active area of research today: estimation of stress orientation and size in

plate interiors for realistic simulations of plate geometry, boundary forces, and rheology (e.g., Richardson *et al.*, 1979; Cloetingh and Wortel, 1986; Govers *et al.*, 1992; Richardson, 1992; Bai *et al.*, 1992; Bird, 1998). Even if the boundary stresses are low, the intraplate stresses can be high due to rheological and geometric effects. It seems that there is some disagreement over the quantitative details, but intraplate shear stress levels are predicted to reach values of 50 MPa in many of these studies. A major emphasis of these current studies is to compare the predicted stress orientations with focal mechanisms, stress provinces, or to geologic history. To conclude, both gravitational loading and boundary force modeling predict high shear stress in some parts of the oceanic lithosphere, but nearly all of these studies have low plate boundary stress values.

5. Direct Stress Measurements

There is no remote sensing instrument that can directly measure stress in the Earth. We must dig a hole to gain access to a rock face, take a “picture,” remove more rock to create additional free surface, then take another “picture” or restore the deformation with a known force. Chapter 34 by Zoback and Zoback reviews all the various direct and indirect methods, thus only a few summary statements are made here.

Some methods, such as overcoring and hydrofracture, do give orientation and size information. Many of the other methods, such as volcanic vent alignments, are better characterized as “indicators.” There are many excellent review papers on direct and indirect stress measurements (e.g., McGarr and Gay, 1978; McNutt, 1987; Hickman, 1991; Chapter 34 by Zoback and Zoback). As summarized in Zoback (1992) only 4% of the data in the World Stress Map Project database give reliable absolute values of stress. As concluded in earlier reviews (see above), direct measurements indicate that upper crust shear stresses in many locales are at the maximum level predicted from Byerlee’s Law.

Most stress measurements in the database only yield a stress “direction”: the orientation of one or more principal axes of the stress tensor. Earthquake focal mechanisms provide the best rock volume integrators and the most numerous global indicators of stress direction. The issue of earthquake stress drop is treated below in a separate section. Many investigators have devised clever techniques to use focal mechanisms from regional seismicity to extract more reliable stress directions (see special issue, Zoback, 1992). One key conclusion from the measurements is that the upper crust has tremendous small-scale variations in stress state due to material heterogeneity, open cracks, and short-wavelength stress loading. For many scientific and engineering applications, these shallow rapid variations in stress are the primary interest. But the small length-scale of these stress concentrations does not contribute to large-scale crustal stress averages. Only consistent trends

across large distances can be related to large-scale tectonic processes. As reviewed by Zoback (1992) and Chapter 34 by Zoback and Zoback, there are large-scale consistent trends in the stress measurements; these areas are called stress provinces. Furthermore, there are several generalizations that can be made about these regimes: plate interiors are dominated by strike-slip and thrust faulting regimes; normal faulting regimes occur in selected continental and oceanic areas with high topography; most stress provinces coincide with physiographic provinces. Zoback (1992) discusses the alignment of stress orientation in some provinces with absolute plate motions, though it seems that there may be other tectonic explanations for these orientations (Richardson, 1992). The World Stress Map Project provides valuable observations that constrain any detailed model of lithosphere stresses.

5.1 Geologic Indicators of Stress

Earthquakes and other stress measurements provide a present-day map of stresses. Several stress indicators used in the World Stress Map Project are geologic observations. Here, I emphasize the future potential of paleo-stress indicators. There is a long tradition in structural geology of paleo-strain indicators, but finding reliable estimates of stress in exhumed rocks is a much more difficult task. Nonetheless, there has been some progress in a variety of techniques (see related papers in special issues, Engelder and Geiser, 1980; Magloughlin and Spray, 1992; Schmid *et al.*, 1999). Given the current controversy surrounding stress levels on major faults and plate boundaries, studies of frictional melting on exhumed faults could be a particularly productive area for future research.

5.2 Stress from the KTB Project

There have been several special projects and deep boreholes that produced stress estimates that are suggestive of high shear stress in the crust. Some of the most recent and compelling direct stress measurements come from the KTB borehole project in Germany. This borehole reached a depth of 9 km in a plate interior. There are several remarkable features about the stress and related measurements at this site (Brudy *et al.*, 1997). First of all, the shear stress at a depth of about 8 km is about 100 MPa. Also, pore fluid pressure is “hydrostatic” down to this depth. Furthermore, the high shear stress level is close to the maximum shear stress allowed by Byerlee’s Law with a friction coefficient of 0.6 and a normal stress that is the lithostatic load minus the pore fluid pressure. There was no tectonic reason to expect high shear stresses in such a setting. The notion that this region is just below the failure stress is further supported by the fluid injection experiment where an incremental pressure increase of roughly 1 MPa induced small earthquakes. Zoback and Harjes (1997) show that focal mechanisms of the induced seismicity are consistent with the measured stress tensor.

To summarize, shear stress orientations in various stress provinces are determined by some aspects of global-scale tectonics. As for stress size, there is evidence from the KTB project and other direct measurements that the upper crust in plate interiors have “high” shear stresses at the frictional failure level. The next section focuses on this aspect.

6. Triggered Earthquakes and Failure Threshold

Earthquakes occur when the shear stress exceeds the failure stress threshold. There is an incubation time between threshold exceedance and earthquake dynamic rupture that ranges from less than a second to years, as documented below [also see special volume edited by Atkinson (1987), Scholz (1990) for discussion, and Ohnaka (1992) for laboratory observations]. This incubation time delay is even more uncertain if triggered creep events or other aseismic processes are responsible for critical loading, and if the failure threshold itself evolves with time (e.g., Sibson, 1990). Empirical studies of earthquake triggering are hampered by the clusters of event occurrence times that are expected from a random Poisson process. Despite all these complexities, there are some well-accepted cases of earthquake triggering at a variety of spatial-temporal time scales. I briefly review these phenomena, starting with the most common example (aftershocks) and ending with the fascinating examples of human-induced seismicity which imply that the Earth's crust must be close to the earthquake failure threshold everywhere.

Aftershocks are the most common and obvious example of triggered seismicity. Aftershocks offer valuable insight to the failure process and there are many empirical and modeling studies (e.g., Yamashita and Knopoff, 1987; Yamanaka and Shimazaki, 1990; Kisslinger, 1993). Although most aftershocks occur on the fault area ruptured by the large earthquake, there is great interest in large earthquakes triggered in adjacent portions of the fault. Scholz (1990) discusses several case histories including the sequence of large earthquakes along the North Anatolian Fault in Turkey (Stein *et al.*, 1997). Many other examples are found in subduction zones, where large-earthquake doublets and multiplets are common in some locales such as the Solomon Islands (Xu and Schwartz, 1993) and Nankai Trough (Ando, 1975). The time delay between these doublets ranges from less than one day to a few years (see Nomanbhoy and Ruff, 1996, for global survey). Since the adjacent plate boundary segments will eventually have a large earthquake, it is fairly easy to understand how stress transfer causes temporal clustering along plate boundaries or major faults. One confusing consequence of large-earthquake doublets and multiplets is that the aftershock areas of adjacent ruptures may overlap (e.g., Tajima *et al.*, 1990), and this hinders the determination of large earthquake recurrence times

(see comments by Nishenko and Sykes, 1993; Jackson and Kagan, 1993).

There is more current interest in aftershocks off the main fault. These “aftershocks” tell us that large volumes of crust surrounding the main fault are also close to their failure threshold. Some great underthrusting earthquakes have triggered intraplate events in the outer-rise (see summary in Christensen and Ruff, 1988). One might expect that great earthquakes would also trigger seismicity in the Wadati–Benioff zone, but any effect is rather subtle (Astiz *et al.*, 1988).

Off-fault aftershocks from strike-slip earthquakes have attracted much interest in the last decade. Two well-documented cases are the great (M_w 8) 1989 Macquarie Ridge event (Das, 1993) and the smaller but extensively studied 1992 Landers, California earthquakes (Anon., 1994). Modeling the static stress changes associated with finite fault models of the Landers events has now expanded to re-examination of other older examples of off-fault triggering (Stein *et al.*, 1997; also see special issue, Harris, 1998). One hypothesis that emerges from these studies is that small shear stress increases trigger seismicity in large crustal volumes.

Remote triggering is even more fascinating where the distances are so large that seismic waves must be the agent of triggering. Remote triggering has been accepted in some parts of the international community for a long time (see references in Diakonov *et al.*, 1990), but this phenomenon is now widely accepted after the spectacular triggering of seismicity throughout western North America after the Landers earthquake (Hill *et al.*, 1993). The physics of how seismic wave dynamic stresses might trigger seismicity is still under investigation, but it is worth noting that most of the triggered seismicity occurred in geothermal regions. Perhaps some fluid–solid coupling process is essential for this effect (see papers in Anon., 1994). Also note that most of the triggered events would not have been detected in most parts of the world due to sparse seismograph network coverage.

The last type of triggering is seismicity induced by fluid injection or reservoir impoundment (see reviews by Simpson, 1986; Chapter 40 by McGarr *et al.*). Hydrofracture experiments produce abundant nanoseismicity, but this activity is not surprising since cracks can generate large stresses. On the other hand, reservoir-induced seismicity sends us a clear message that the Earth's crust is close to shear failure in most continental settings. The gravitational load from most reservoirs changes shear stresses by 1 MPa or less. Seismicity may be induced directly by this surface load, or by the changes in fluid pore pressure (Simpson, 1986). Regardless of the details, the fact that 1 MPa water surface loads trigger seismicity compels us to conclude that stress in most of the Earth's crust is close to the failure threshold.

Many different aspects and consequences of earthquake triggering are addressed in the Harris (1998) special issue. The well-known lack of correlation between tidal stresses and earthquake occurrence (Vidale *et al.*, 1998) is puzzling and

admits several different interpretations. Theoretical and observational studies on the spatial-temporal evolution of failure thresholds and incubation time should receive more research effort in the future. There is currently great interest in holistic interpretations of the inference that shear stress is close to failure stress in most of the Earth's crust. One perspective is that the Earth's lithosphere presents an example of a system self-maintained at the critical state. In this context, the critical state is shear stress at the failure threshold stress (Bak and Tang, 1989; Sornette *et al.*, 1990; Rundle *et al.*, 1995; Grasso and Sornette, 1998). If we enlarge our definition of failure to include some aseismic processes, then perhaps most of the Earth is "at failure." It is appropriate that one of the more successful quantitative applications has been the critical taper explanation for accretionary prisms in subduction zones – which can be viewed as a big sand pile (see review by Dahlen, 1990). Recall that the detailed tectonic models described in Section 4 do not predict high shear stresses everywhere. Those regions of low stress might still be close to failure due to various processes lowering the failure threshold. Plate boundaries are places of low shear stress and low failure thresholds. The KTB borehole intraplate site is an example of high failure threshold but also high shear stress. In the future, perhaps we should study places of low shear stress and no seismicity to test the notion that the Earth's lithosphere is critical everywhere.

7. Earthquake Stress Drops and Plate Boundary Stresses

Earthquakes are the primary stress failure indicators in the Earth. When shear stress across a locked fault reaches the failure stress, the fault slips to reduce shear stress on the fault plane, though stress might increase in adjacent regions. This overall average reduction in shear stress on the ruptured fault is the static stress drop. Static stress drop provides a lower bound on lithospheric shear stress. Below, both static and dynamic stress drop results for earthquakes are reviewed. The key results are that recent studies reaffirm the "rule" that static stress drops are about 1–10 MPa for large plate boundary earthquakes, and average dynamic stress drops from two techniques – dynamic stress drop and radiated wave energy – are no larger than static stress drops. In detail, there are some systematic trends within the scatter of stress drops, but that should not change the primary conclusion that stress drops of large earthquakes are "low."

Shear stress at a locked plate boundary can slowly increase until it reaches the failure stress. The failure stress level can be represented by the static coefficient of friction. Slip on the fault can occur either as creep or as earthquakes; the behavior is controlled by the dynamic coefficient of friction during slip. If the dynamic coefficient of friction is the same value or

larger, than the static coefficient of friction, then creep is the resultant behavior. If the dynamic coefficient of friction drops below the static value fast enough, then we have an earthquake. The friction constitutive laws are covered in Chapter 32 by Lockner and Beeler. The dynamic stress drop is controlled by this complicated frictional behavior, and it is likely to vary in space and time as the rupture front sweeps across the fault. Dynamic stress drop has the potential to reveal more earthquake physics, but current global surveys of dynamic stress drop assume simple models with uniform dynamic stress drop.

7.1 Static Stress Drop

Static stress drop is the simplest measure of the overall reduction in shear stress due to slip on the fault zone. It is the difference between the average shear stress on the fault zone before and after the earthquake (Fig. 4). Since the stress drop of real earthquakes varies across the fault area, the overall static stress drop is a slip-weighted average of the spatially variable stress drop. Seismologists typically use simple constant stress drop models to estimate earthquake stress drops. Regardless of the details of fault geometry and slip distribution, the basic formula for stress drop is:

$$\Delta\sigma_{st} = c \mu D/X \quad (1)$$

where D is the average slip over the faulted area (A), X is the characteristic length of the fault area, μ is the elastic shear modulus, and c is a geometric constant that is close to one (if X is properly chosen). Since seismic moment (M_o) for most large earthquakes can be reliably determined from seismic waves, the Eq. (1) can be rewritten as:

$$\Delta\sigma_{st} = c \mu DA/(XA) = c M_o/(XA) \quad (2)$$

This formula shows that three quantities are needed to calculate stress drop: a measurement of the seismic moment, some estimate of the fault area (A), and then some appropriate choice for the characteristic fault dimension. Whereas the choice of X presents an interpretation problem, it is the estimation of A that presents practical difficulties and introduces large errors into stress drop estimates. The best estimates of A combine geodetic, aftershocks, and seismic wave data, but most estimates of A are based solely on drawing a rectangle or ellipse around aftershocks. This technique is trustworthy for great earthquakes with fault zones more than 100 km across, but its reliability decreases as fault dimensions decrease toward the epicenter location accuracy and as the number of aftershocks decreases. Since the fault area of magnitude 7 earthquakes is expected to be just a little over 10 km across, this aftershock technique is limited just to great earthquakes if we desire a uniform global study.

It is possible to extract the fault length from source-time functions. If a large earthquake ruptures a long fault zone in a unilateral fashion, the directivity seen in the source time

FIGURE 4 Illustration of how the ratio of dynamic to static stress drop partitions earthquake strain energy into wave and friction energy. Three possible behaviors of dynamic fault friction are shown. Each graph shows the fault-averaged history of fault friction stress (σ) as a function of fault slip (X), where final earthquake displacement is D .

functions from azimuthally distributed stations can be quantitatively exploited to determine the longer fault dimension. Other means are usually used to estimate the shorter fault dimension. This rupture process method is time-consuming and difficult, and produces reliable results for just a few earthquakes. Thus, in most studies, just the overall source time function duration is used to estimate fault length. This simple method can be applied to the largest number of events, but the rupture velocity and fault aspect ratio must be assumed.

Previous reviews have combined all the various estimates to compare stress drops of all earthquakes, small to large and deep to shallow (Aki, 1972; Kanamori and Anderson, 1975; Abe, 1982; Hanks, 1977; Purcaru and Berckhemer, 1982; Abercrombie, 1995). These studies have given us one of the key tenets of seismology that stress drop is “approximately constant” for earthquakes of all types and sizes. In detail, “approximately constant” means that stress drop estimates typically fall in the range of 0.1–10 MPa (1–100 bars), with an occasional report of much higher values for smaller events.

There has been an interpretation problem for earthquake stress drop. For small earthquakes, a circular fault shape is thought to be a good model, hence the static stress drop is:

$$\Delta\sigma_{st} = (7/16) M_o / r^3 \quad (3)$$

where r is the fault radius. Indeed, systematic studies of small earthquakes show that the ratio of moment to radius cubed is nearly constant. In detail, most studies of small events use source time function duration as a proxy for radius, thus the empirical result is that duration (d) increases as moment to the one-third power, i.e., $d \propto M_o^{1/3}$.

For large earthquakes, the down-dip fault width is limited by the depth extent of the seismogenic zone. Hence, above a certain size, earthquakes all have the same fault width, but have different along-strike fault lengths. For an elongated fault shape, the characteristic length should be fault width, hence the stress drop formula is:

$$\Delta\sigma_{st} = c M_o / (W^2 L) \quad (4)$$

where W and L are fault width and length. For empirical studies, the above formula predicts that for constant stress drop: $L \propto M_o^{1.0}$. In the following subsections, we briefly review empirical results for earthquakes in different tectonic settings.

7.1.1 Shallow Intraplate Earthquakes

Shimazaki (1986) showed observations from intraplate events in Japan that show a change in fault length versus moment scaling at an earthquake size of about $M_w = 6.7$. For the larger earthquakes, Shimazaki (1986) found that the ratio of (M_o/L^2) is constant (in detail, $L \propto M_o^{0.44}$). If stress drop is constant for these large events, then Shimazaki’s (1986) results imply that L is the characteristic length for stress drop, rather than W (see Scholz, 1990, for extended discussion of this point). Alternatively, if the above expectation in Section 7.1 for $L \propto M_o^{1.0}$ scaling is correct, then stress drop increases with fault length for these events. Regardless of these scaling difficulties, Scholz (1990) reviews evidence that shallow intraplate events have stress drops of about 10 MPa, i.e., at the higher end of the overall observed range.

7.1.2 Strike-Slip Earthquakes

The change in fault aspect ratio from equant to elongated is particularly severe for strike-slip faults. The width of the

seismogenic zone is about 15 km, but fault length can be hundreds of kilometers for the largest strike-slip events. For the case of long strike-slip faults that reach the surface, the geometric constant in the above formula is $(2/\pi)$, hence:

$$\Delta\sigma_{st} = (2/\pi) M_o / (W^2 L) \quad (5)$$

If this formula is correct, empirical studies of large strike-slip earthquakes should find the $L \propto M_o^{1.0}$ scaling. Romanowicz (1992) shows that this is true for strike-slip earthquakes with vertical fault planes and seismic moments larger than 1×10^{20} Nm (M_w 7.3). If we use the bounds on the $L \propto M_o^{1.0}$ scaling for large events in Romanowicz (1992), then stress drop ranges from 3 to 7.5 MPa. This reaffirms the “rule” that stress drop is constant and falls in the range of 1–10 MPa. One notable exception to this rule is the 1989 Macquarie Ridge earthquake. Although initial stress drop estimates were 30 MPa and higher, later reevaluation by Das (1993) has reduced the overall stress drop to about 12 MPa.

7.1.3 Subduction Underthrusting Earthquakes

The shallow dip angle of the plate interface in subduction zones allows the down-dip seismogenic width to be 150 km or so. Therefore, it is only the greatest underthrusting earthquakes with M_w more than 8 that have elongated rupture areas. For all other large underthrusting events, a good choice for the characteristic length is to take the geometric average of width and length (Aki, 1972). With this choice, $X = A^{1/2}$, and the stress drop formula is:

$$\Delta\sigma_{st} = c M_o / A^{3/2} \quad (6)$$

In this case, the empirical scaling would be: $L \propto M_o^{2/3}$. Aki (1972) and Kanamori and Anderson (1975) show that large subduction earthquakes are consistent with a constant stress drop of about 1–10 MPa using the above formula. The greatest subduction earthquakes have ratios of fault length to width greater than 4, which means that stress drop characteristic length should be fault width and the empirical length scaling should be $L \propto M_o^1$. However, the best-fit observed empirical scaling between length and moment is $L \propto M_o^{0.4}$ for event size of $2\text{--}2000 \times 10^{20}$ Nm. A curious coincidence is that the scaling exponents for large intraplate (see Shimazaki, 1986) and great underthrusting events are 0.44 and 0.4, and this coincidence becomes even more curious since Tanioka and Ruff (1997) found that for recent global seismicity, the scaling exponent for source time function duration versus moment is about 0.4, i.e., $d \propto M_o^{0.4}$. These results imply that the assumed stress drop formula for large events misjudges the width and length scaling, or that stress drops do vary with earthquake size, or both. However, even if the extreme $L \propto M_o^1$ scaling is adopted to calculate stress drops, the quantitative results are that stress drop estimates from large to great underthrusting earthquakes are in the range of 0.2–9 MPa.

7.1.4 Deep Slab Earthquakes

Few aftershocks are recorded for deep Wadati–Benioff zone earthquakes (Frohlich, 1989), thus most static stress drop estimates are based on source–time functions. Empirical studies suggest that duration versus moment scaling for deep events is similar to that for shallow events, after correction for the larger shear modulus (e.g., Tanioka and Ruff, 1997; Bos *et al.*, 1998). Three large deep earthquakes have occurred since 1994 to spark new interest in deep earthquake rupture. Aftershock and rupture process studies have defined the rupture area for these events. As reviewed in Goes *et al.* (1997), the resultant static stress drops for these events are: 1994 Fiji, 7 MPa; 1996 Flores, 16 MPa, and 1994 Bolivia, 71 MPa (other estimates for Bolivia are even higher, see special issue, Wallace, 1995). Although all three events have source time function durations that follow the expected scaling rule, the Flores and Bolivia events have smaller than expected rupture areas (see references in Goes *et al.*, 1997), hence higher stress drops. These large deep events have prompted many papers and reevaluation of deep earthquake processes (e.g., Kanamori *et al.*, 1998). For our purposes here, it must be acknowledged that stress drop for large deep earthquakes can be “high,” i.e., more than 50 MPa. Most stress drop compilations have a few small events with “high” stress drops, but those values can be ignored after consideration of error estimates. However, the extensive data sets and studies of the 1994 Bolivia event (Wallace, 1995) provide a reliable “high” stress drop.

7.1.5 Summary of Static Stress Drops

In conclusion, there are some problems in large earthquake scaling rules, but the observations still allow the following simple summary statement (with a notable exception): all large earthquakes have a static stress drop of 0.1–10 MPa (except for some large deep-slab earthquakes with static stress drops closer to 100 MPa). These static stress drop values represent a clear lower bound on shear stresses, yet they are close to estimates of total shear stress on plate boundaries from tectonic modeling studies.

7.2 Dynamic Stress Drop and Radiated Wave Energy

Dynamic stress drop measures the difference between initial stress and fault friction stress while the fault is slipping (Fig. 4). If static stress drop is just a partial stress drop and if dynamic friction stress is less than the final stress, then dynamic stress drop is larger than static stress drop. One of the suggestions to escape the “San Andreas heat flow paradox” (discussed in a later section, also see Chapter 35 by Brune and Thatcher) is that dynamic stress drop is much greater than static stress drop. Two methods can be used to estimate the ratio of dynamic to static stress drop: (1) “direct” estimate of dynamic stress drop; (2) measure the ratio of total radiated seismic wave energy to

the “Orowan” radiated wave energy (see Fig. 4). It is difficult to reliably determine dynamic stress drop directly, and even more difficult to measure radiated wave energy.

Kikuchi and Fukao (1988) calculated radiated seismic wave energy for several great earthquakes and found that the energy was less than expected. “Effective seismic efficiency” (Kikuchi, 1992) is the wave-to-Orowan energy ratio described above. For the dynamic friction behavior depicted in Figure 4, ζ is the “effective seismic efficiency” [unfortunately, there is some notation confusion with seismic efficiency, see Kikuchi (1992), Kanamori (1994), and McGarr (1999)]. Kikuchi shows that “effective seismic efficiency” is less than 1 for the events in the Kikuchi and Fukao (1988) study, hence dynamic stress drop is less than static stress drop. Choy and Boatwright (1995) used a different method than Kikuchi and Fukao, but they found low values for “apparent stress drop,” which implies low dynamic stress drop. Tanioka and Ruff (1997) found that source time function systematics for global seismicity are roughly consistent with the results in Kikuchi and Fukao (1988) and Choy and Boatwright (1995). On the other hand, Kanamori *et al.* (1993) used an empirical–theoretical hybrid technique to study California earthquakes, and found that seismic efficiency is closer to 1. Winslow and Ruff (1999) used a different hybrid technique for large deep Wadati–Benioff earthquakes, and found that “effective seismic efficiency” is less than or equal to 1.

A recent study by Ruff (1999) produced “direct” estimates of dynamic stress drop for global seismicity. Ruff (1999) found that dynamic stress drops were scattered from 0.1 to >10 MPa. Thus, the overall scatter in dynamic stress drops encompasses the scatter in static stress drops discussed above. However, the question remains if there is some systematic shift between stress drops for the same events. Figure 5 addresses this question by plotting both static and dynamic stress drop estimates for the same large underthrusting earthquakes. For most events, the dynamic stress drop estimate is

equal to or smaller than the static stress drop for the same earthquake (note the two exceptions in Fig. 5). Overall, these results favor the “hi-friction” rupture scenario in Figure 4c.

To summarize all these results that can be translated into the ratio of dynamic stress drop to static stress, observational studies of large earthquakes find that this ratio is less than 1. Since dynamic stress drops are the same or smaller than static stress drops, absolute shear stress levels that are significantly higher than earthquake stress drops must produce significant frictional heating during earthquake slip.

8. Heat Flow Constraints on Plate Boundary Stress

Earthquake stress drops give us a lower bound on shear stress acting along plate boundaries. To find the total shear stress, we also need to measure the average frictional stress level acting on the fault while it slips. In the simplest model of a creeping plate boundary, the average frictional stress level multiplied by the slip velocity gives the heat production per unit area of the fault zone, and this increases the temperature of the fault zone so that sufficient heat energy is conducted away to balance the heat production. Soon after the advent of plate tectonics, it was realized that strike-slip plate boundaries were ideal places to look for the heat flow anomaly from frictional heating. Given the long-term slip rate along a fault and the hypothetical depth distribution of friction shear stress, it is straightforward to predict the shape and strength of the surface heat flow anomaly. Observations show no heat flow anomaly of the correct shape across either the creeping or seismically active portions of the San Andreas Fault. The upper bound on frictional shear stress is about 10 MPa (see Brune *et al.*, 1969; Lachenbruch and Sass, 1992; Sass *et al.*, 1997). This celebrated San Andreas heat flow result is still one of the strongest arguments for low shear stress on plate boundaries.

Dip-slip faulting presents a more difficult heat flow experiment than strike-slip faults (Molnar and England, 1990). Thermal models are more complex for subduction plate boundaries as they must include heat advection and time-dependent thermal structure in the down-going slab. Early thermal models simply assumed high stress levels since one of the objectives was to melt subducted material. Today, most models for island arc volcanism presume that volatiles are fluxed from the slab into the mantle to cause melting (Peacock, 1996), thus there is no a priori reason to assume high shear stresses. If we know the physical properties and thermal structure of the subducting slab, then frictional heating may be determined by matching forearc heat flow observations. In the most comprehensive global effort to date, Tichelaar and Ruff (1993) concluded that the average frictional shear stress level in the world’s strongly coupled subduction zones could range from 20 to 35 MPa. This shear stress estimate seems to be

FIGURE 5 Comparison of static and dynamic stress drop estimates for many of the largest underthrusting plate boundary earthquakes that have occurred since 1963. Each earthquake is represented by a connected pair of filled and open dots, representing static and dynamic stress drop, respectively.

significantly above the stress drop of large underthrusting events, and it is also above the shear stress estimates for the San Andreas fault. On the other hand, detailed thermal studies for particular subduction zones may find different values (e.g., Hyndman *et al.*, 1995; Wang *et al.*, 1995). For the future, we need to find new and better constraints on subduction zone thermal structure.

To summarize, plate boundary heat flow studies apparently constrain shear stresses to be less than 10 MPa along the San Andreas fault and less than 35 MPa in subduction zones. These values are less than shear stresses expected for frictional failure from lithostatic pressure and Byerlee's Law. Thus, there has been considerable debate on how to reconcile this discrepancy. If we also consider the modeling results on plate tectonics, geoid anomalies, and boundary forces, it seems that we must accept "low" plate boundary stresses. The next section reviews the efforts to explain why plate boundaries are weak.

9. Why are Plate Boundaries Weak?

Detailed studies of the San Andreas system show that it is a weak fault in two respects: shear stress on the fault is low, and the orientation of the maximum horizontal principal stress is nearly orthogonal to the fault (see Chapter 32 by Lockner and Beeler and papers in Zoback and Lachenbruch, 1992). Thus, the San Andreas fault must be much weaker than nearby faults with an orientation more favorable for failure. The current debate on stress state is largely centered on the question of how can plate boundaries be so weak? Most current answers to this question use water in various roles. Although most of this section is focused on water, some of the alternative interpretations of the low San Andreas heat flux are reviewed first.

9.1 Explanations without High Pore Pressure

One explanation that combines high shear stresses and low heat flow is that dynamic stress drop is a factor of ten higher than static stress drop. Although there may be several theoretical models that can produce these high dynamic stress drops (see references in Brune *et al.*, 1993), observations will ultimately decide the fate of this mechanism. As reviewed above (Section 7), global studies show that dynamic stress drop is *not* larger than static stress drop. Of course, one could still argue for special circumstances along the San Andreas fault. Hence we must wait and measure the dynamic stress drop of future great earthquakes along the San Andreas fault. In the meantime, studies of the 1989 Loma Prieta event suggest low shear stress (e.g., Zoback and Beroza, 1993).

Large dynamic stress drop is not relevant for the creeping sections of the San Andreas. The most direct explanation for both the creeping and seismogenic portions is to just accept that the fault has a very low friction coefficient. The lithostatic

vertical normal stress at 15 km depth, i.e., the bottom edge of most strike-slip faults, is about 400 MPa. Then the friction coefficient must be 0.05 to give a failure shear stress of 20 MPa. Even if hydrostatic pressure is subtracted from the above normal stress, a friction coefficient of 0.08 is required to keep shear stress at 20 MPa. In subduction zones where the seismogenic zone extends to 40 km depth, the friction coefficient must be less than 0.10 even for the higher shear stress estimate of Tichelaar and Ruff (1993). For comparison, lubricants such as MoS₂ and Teflon have a friction coefficient of 0.06. Laboratory experiments indicate that candidate geologic materials—even low-friction choices—are unlikely to have such low friction coefficients at crustal conditions (see Chapter 32 by Lockner and Beeler).

One idea to achieve these low friction coefficients is to use "roller bearings" between the fault surfaces. Although there must be low-friction lubricants around the "rollers," it seems that there is both experimental (Brune and Anooshehpour, 1997) and numerical (Mora and Place, 1998) support that fault "rollers" can reduce the large-scale friction coefficient of the fault. [See Scholz (1996) for arguments against this mechanism as the solution for the San Andreas heat flow paradox.]

The final alternative explanation is that plate boundary shear stress is high and "friction" energy is high, but that this "friction" energy does not appear as high heat flow above the fault. At one extreme, this argument contends that something is wrong with the interpretation of heat flow in the San Andreas region. This series of arguments and counter-arguments has a long history, and the following reviews and special issues address this issue: Hanks and Raleigh (1980); Hickman (1991); Zoback and Lachenbruch (1992); Molnar (1992); Scholz (1996). This complicated issue can be easily circumvented in two ways: (1) global-scale tectonic and gravitational modeling prefers low shear stresses on plate boundaries; (2) current ideas that use water in plate boundaries seem to work with low shear stresses. Thus, it seems reasonable to accept the constraint that shear stress is low on the San Andreas fault and subduction zone plate boundaries.

9.2 Water and Weak Plate Boundaries

The admittance of water into plate boundaries opens an area of complex mechanical and chemical interactions that affect stress and earthquake occurrence (see papers in special volumes: introduction by Evans and Wong, 1992; Hickman *et al.*, 1995). Connections between water and faulting appear throughout the geologic literature, but the on-going low/high stress debate has focused more attention on water in the last decade. The compositional complexities of pore fluids are not discussed here; "water" includes all components of pore fluids. The chemical and mechanical role of water is an active research topic, so conclusions are subject to change. A brief overview of current models that may explain weak plate boundaries is given here, together with some of the caveats and complications.

The simplest role of water is that pore fluid pressure reduces the normal stress acting across-fault planes. Pore pressure does not change the shear stress. It is supposed that typical friction coefficient values of 0.5–1.0 can be applied to the ratio of shear stress to effective normal stress (effective normal stress is the normal stress minus the pore pressure). As fluid pressure increases to near the value of the least compressive principal stress, slip can occur with shear stress values less than 10 MPa. Effective normal stress is a simplistic treatment of the solid–water mechanical interaction (see discussion below), but it should work for shallow crustal depths. In most cases, we presume that the relative sizes of the principal stresses follow the Anderson (1942) model for the faulting regime. In a thrust setting, σ_{zz} is the least compressive principal stress, and as fluid pressure on a shallow-dipping fault approaches σ_{zz} , the overlying rock nearly “floats” on the water layer and the thrust fault can move at low shear stress. Hubbert and Rubey (1959) used this device to explain some aspects of shallow thrust faults (see Fig. 6b).

Today, high fluid pressure in subduction zones has become a well-accepted explanation for low shear stress. Although accretionary prisms are quite complex, a wealth of both observational and modeling studies allow the conclusion that de-watering of subducted sediments can sustain high fluid pressures down to a depth of several kilometers, perhaps even ten kilometers (see reviews and extensive references in Von Huene and Scholl, 1991; Moore and Vrolijk, 1992). At the deeper depths of the seismogenic zone, there are few observational and modeling constraints on the existence and nature

of interface fluids (Moore and Vrolijk, 1992). Most researchers are willing to accept the notion of high fluid pressures down to a depth of 40 km, though the primary justification is simply that shear stresses are low in the seismogenic portion of subduction zones (see Wang and He, 1999, and references therein). In the future, subduction zones must be the subject of more studies on fluids.

High fluid pressure may explain low shear stress in continental normal and strike-slip faulting environments, but there are some difficulties. First, the fluid pressure must shift from hydrostatic toward lithostatic pressure in the first few kilometers of the crust (see Fig. 6). Since fluid flow should reduce this higher pressure, this topic immediately involves permeability structure and crustal fluid flow. Sibson (1990, and earlier references) discusses how lithostatic fluid pressure may occur in general, and for the San Andreas region in particular. Next, the San Andreas system shows an additional problem in that the maximum horizontal compressive stress is nearly orthogonal to the fault trace. Sibson (1990) shows that in these “severely misaligned” fault situations, high fluid pressure causes hydro-fractures before it fulfills its role of shear stress reduction on the main fault plane. Indeed, it is now a well-accepted conclusion that fluid pressure cannot be at a sufficiently high pressure throughout the crust all the time. To retain water as the explanation for low shear stress, we must keep high fluid pressure in the fault zone without leakage into the surrounding rock. Two related mechanisms that accomplish this feat have been suggested. Byerlee (1990) uses high pressure water trapped in fault zone gouge.

FIGURE 6 High fluid pressure in fault zones. (a) Hydrostatic and lithostatic pressure and various bounds on horizontal principal stresses as a function of depth. For strike-slip faults with unfavorable stress orientation, such as the San Andreas, the high fluid pressure must be contained within the fault zone (b), and this requires certain combinations of permeability structure, fluid flow and sources.

Rice (1992) has developed the most complete model that addresses all aspects of stress regime, anisotropic permeability, fluid flow, and deep crustal source. A key aspect of the Rice (1992) model is that the stress tensor for the narrow fault zone region is different from the stress tensor for the surrounding crust (the Byerlee, 1990, model also makes use of variable stress). The fault zone stress tensor has a different geometry and size of the principal stresses such that the higher pore pressure in the fault zone does not cause hydro-fracture in the surrounding rock. It appears that these two models are viable explanations for low shear stress, though hydrological implications have not been fully tested. The question then becomes: Is fault zone high fluid pressure the correct explanation? Some people have objected to these models because of the requirement that the Earth find these “special” stress/fluid pressures states at all plate boundaries. But in his model, Rice (1992) outlined how fault systems might evolve toward this special stress state. Sibson (1990) and Nur and Walder (1992) and others (see papers in Hickman *et al.*, 1995) have advocated the intrinsic time dependence of the coupled earthquake/fluid system. Although this view makes formal solutions more difficult, it provides opportunities for the system to evolve toward a special stress state. Indeed, it seems that future work in the stress state of plate boundaries must further develop fault evolution scenarios to show that a particular mechanism is not only possible, but that it is a robust system state for “real” fault systems.

9.3 Caveats and Complications with Water in Faults

We now turn to a quick appraisal of the complexities in a time-dependent coupled earthquake–water system (Sibson, 1973; Fyfe *et al.*, 1978; Nur and Walder, 1992). The mechanics of the coupled solid–fluid continuum are complex (e.g., Rice and Cleary, 1976), and allowance for time dependence in stress and material properties such as porosity and permeability make for even greater complexity (Yamashita, 1997). There is a large industrial effort in these calculations for problems such as sedimentary basin development, reservoir management, and other engineering applications. The fully coupled earthquake–fluid problem is also a very complex problem. Here, brief mention is made of one complication that may reduce the utility of fluid pressure in reducing the effective normal stress.

In the usual derivation of Amonton’s or Byerlee’s Law (see Scholz, 1990), the rock-to-rock contacts across an interface bear both the normal and shear stresses. If the pores are filled with a fluid, then the pores help to support some of the normal stress, but all the shear stress is carried by the rock contacts. As discussed in Jaeger and Cook (1979), the common usage of effective normal stress assumes that the actual area of rock contacts is a small fraction of the total fault area; this is certainly a good assumption at low confining pressure. If a water-filled contact surface is subjected to higher pressure and

temperature, pore volume shrinks as rock contact area grows. It is difficult to calculate exactly how the pore surface area shrinks; one must construct various surface roughness models, then use empirical or theoretical models to compress the system (Gavrilenko and Gueguen, 1993). Since the pressure at the seismogenic down-dip edge in subduction zones can be more than 1000 MPa, pore collapse could be a serious problem. In the limit of a small pore area along the fault surface, pore fluid pressure cannot reduce the value of the overall normal stress. In his model for strike-slip faults, Rice (1992) avoids this problem by quoting observational evidence that an extensive fluid region exists in the lower crust, with the immediate consequence that water in these pores must be very close to lithostatic pressure. In subduction zones, it is presumed that any water in the seismogenic zone was carried down in the oceanic crust, thus there is less freedom to make a dense network of pores with the fluid at lithostatic pressure.

9.4 Final Thought on Water in Faults

A final philosophical objection to water in fault zones is that admittance of water makes the problem too complex and obscure. We first seek the most elegant, i.e., simple, solution to scientific problems. For the problem of reconciling low shear stress with Byerlee’s Law, I suppose that the elegant solution would be to discover that all plate boundaries are lined with Teflon. However, there are many Earth Science questions that have complex, inelegant, and “messy” answers. “What controls the climate?” provides a good example of how the answer to an important global-scale question involves the interaction of many obscure processes and minor constituents. State of stress on plate boundaries may be an analogous problem, and we have to accept that minor constituents such as water may play a dominant role in the interlinked processes that control shear stress on faults.

10. Conclusions

The support of gravitational loads on and within the Earth provides constraints on minimum shear stress levels. The classic Jeffreys argument shows that isostatically compensated mountains require shear stresses of 75 MPa somewhere in the lithosphere (see Fig. 7).

Buoyancy sources associated with plate tectonics require shear stresses of at least 10 MPa. Global force balance calculations find acceptable solutions with plate boundary stresses of 10 MPa, but some plate interiors may have shear stresses close to 100 MPa. Many models of subducted slab mechanics also produce internal stresses of 100 MPa. Detailed regional modeling efforts of subduction zones with tectonic and buoyancy forces find self-consistent models with low stress levels on the plate interface.

FIGURE 7 Cartoon summary of stress state of the Earth. The length-scale varies from a planetary view at the left to uppermost crust details at the right.

The World Stress Map Project has defined stress provinces where large-volume determinations of the orientation of shear stress are consistent. These directions are mostly consistent with global-scale tectonic models of either lithospheric basal drag or plate boundary forces. Direct stress measurements find shear stresses in the upper crust at the failure value predicted by Byerlee's Law. Many stress indicators show that the maximum horizontal principal stress is nearly orthogonal to the San Andreas fault.

Large earthquake stress drops are in the range of 0.1–10 MPa; intraplate events are biased toward the top of this range, whereas large subduction zone earthquakes are biased toward the lower part of the range. Recent large deep earthquakes have stress drops as high as 70 MPa; this high value is compatible with some models of subduction that predict high intraplate stresses.

The absence of a heat flow anomaly across the San Andreas fault argues for low shear stress, 10 MPa or less, unless there is some other process at work that absorbs the energy. Global-scale subduction zone thermal models produce overall shear stress levels of about 35 MPa, though there is much more uncertainty in this constraint as specific studies (e.g., Cascadia, Wang *et al.*, 1995) propose even smaller stress levels.

The stress state that emerges from these constraints is that plate interiors may have high levels of shear stress, but that plate boundaries and other major active faults have low shear stress. Faults that slip the most are the weakest. It seems that water in fault zones may play a key role by reducing the effective normal stress so that the fault will slip with low shear stresses. There are many other effects of water in fault zones, and thus more exploration is required. There are still many

geologic and geophysical questions as to exactly how the Earth system evolves to make this happen.

Many observations indicate that the upper lithosphere of the Earth is close to failure stress. Some of the more intriguing evidence comes from reservoir-induced seismicity, where small stress perturbations cause earthquakes away from plate boundaries. Note that water pore pressure may play a role for induced seismicity. This empirical evidence meshes nicely with some theoretical views that the entire Earth is at the failure threshold stress. This holistic view provides a simple summary of the stress state of the Earth: Stress is everywhere close to the failure stress, whatever that is!

State of Stress in the Earth's Lithosphere

Mark D. Zoback

Stanford University, Stanford, USA

Mary Lou Zoback

US Geological Survey, Menlo Park, USA

The state of stress in the lithosphere is the result of the forces acting upon and within it. Knowledge of the magnitude and distribution of these forces can be combined with mechanical, thermal and rheological constraints to examine a broad range of lithospheric deformational processes. For example, such knowledge contributes to a better understanding of the processes that both drive and inhibit lithospheric plate motions as well as the forces responsible for the occurrence of crustal earthquakes – both along plate boundaries and in intraplate regions.

Although the topic of this chapter is the state of stress in the Earth's lithosphere, the comments below come primarily from the perspective of the state of stress in the brittle upper crust. As defined by the depth of shallow earthquakes, the brittle crust extends to ~ 15 – 20 km depth at most continental locations around the world. This perspective is adopted here because nearly all the data available on lithospheric stress come from the upper crust of continents. Furthermore, in the sections that follow, we argue that, to first order, the state of stress in the brittle crust results from relatively large-scale lithospheric processes so that knowledge of crustal stress can be used to constrain the forces involved in these processes.

1. Basic Definitions

Stress is a tensor, which describes the density of forces acting on all surfaces passing through a point. In terms of continuum mechanics, the stresses acting on a homogeneous, isotropic body at depth are describable as a second rank tensor, with nine components (Fig. 1a).

$$\bar{S} = \begin{vmatrix} s_{11} & s_{12} & s_{13} \\ s_{21} & s_{22} & s_{23} \\ s_{31} & s_{32} & s_{33} \end{vmatrix} \quad (1)$$

The subscripts of the individual stress components refer to the direction that a given force is acting and the face of the unit cube upon which the stress component acts. Thus, in simplest terms, any given stress component represents a force acting in a specific direction on a unit area of given orientation. As illustrated in Figure 1a, a stress tensor can be defined in terms of any arbitrary reference frame. Because of equilibrium conditions

$$s_{12} = s_{21} \quad s_{13} = s_{31} \quad s_{23} = s_{32} \quad (2)$$

so that the order of the subscripts is unimportant. In general, to fully describe the state of stress at depth, one must estimate six stress magnitudes or three stress magnitudes and the three angles that define the orientation of the stress coordinate system with respect to a reference coordinate system (such as geographic coordinates, for example).

We utilize the convention that compressive stress is positive because *in situ* stresses at depths greater than a few tens of meters in the Earth are *always* compressive. Tensile stresses do not exist at depth in the Earth for two fundamental reasons. First, because the tensile strength of rock is generally quite low, significant tensile stress cannot be supported in the Earth. Second, because there is always a fluid phase saturating the pore space in rock at depth (except at depths shallower than the water table), the pore pressure resulting from this fluid phase would cause the rock to hydraulically fracture should the least compressive stress reach a value even as low as the pore pressure.

Once a stress tensor is known, it is possible to evaluate stresses in any coordinate system via tensor transformation. To accomplish this transformation, we need to specify the direction cosines (a_{ij} , as illustrated in Fig. 1b) that describe the rotation of the coordinate axes between the old and new coordinate systems. Mathematically, the equation which

FIGURE 1 Definition of stress tensor in an arbitrary cartesian coordinate system, rotation of stress coordinate systems through tensor transformation and principal stresses as defined in a coordinate system in which shear stresses vanish.

accomplishes this is

$$\bar{S}' = \bar{A}^T \bar{S} \bar{A} \quad (3a)$$

where

$$\bar{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \quad (3b)$$

The ability to transform coordinate systems is of interest here because we can choose to generally describe the state of stress in terms of the principal coordinate system. The principal coordinate system is the one in which shear stresses vanish and only three principal stresses, $S_1 \geq S_2 \geq S_3$ fully describe the stress field (as illustrated in Fig. 1c). Thus, we have diagonalized the stress tensor such that the principal stresses correspond to the eigenvalues of the stress tensor and the principal stress directions correspond to its eigenvectors.

$$\bar{S}' = \begin{bmatrix} S_1 & 0 & 0 \\ 0 & S_2 & 0 \\ 0 & 0 & S_3 \end{bmatrix} \quad (4)$$

The reason this concept is so important is that as the Earth's surface is in contact with a fluid (either air or water) and cannot support shear tractions, it is a principal stress plane. Thus, one principal stress is generally expected to be normal to

the Earth's surface with the other two principal stresses acting in an approximately horizontal plane. Although it is clear that this must be true very close to the Earth's surface, compilation of earthquake focal mechanism data and other stress indicators (described below) suggest that it is also generally true to the depth of the brittle-ductile transition in the upper crust (Zoback and Zoback, 1980, 1989; Zoback, 1992; Brudy *et al.*, 1997). Assuming this is the case, we must define only four parameters to describe the state of stress at depth; one stress orientation (usually taken to be the azimuth of the maximum horizontal compression, S_{Hmax}) and three principal stress magnitudes: S_V , the vertical stress, corresponding the weight of the overburden; S_{Hmax} , the maximum principal horizontal stress; and S_{hmin} , the minimum principal horizontal stress. This obviously helps make stress determination in the crust a tractable problem.

In applying these concepts to the Earth's crust, it is helpful to consider the magnitudes of the greatest, intermediate, and minimum principal stress at depth (S_1 , S_2 , and S_3) in terms of S_V , S_{Hmax} and S_{hmin} in the manner originally proposed by E.M. Anderson (Anderson, 1951). This is illustrated in Figure 2. There are a number of simple, but fundamental points about these seemingly straightforward relations.

First, the two horizontal principal stresses in the Earth, S_{Hmax} and S_{hmin} , can be described relative to the vertical principal stress, S_V , whose magnitude corresponds to the overburden. Mathematically, this is equivalent to integration

FIGURE 2 E.M. Anderson's classification scheme for relative stress magnitudes in normal, strike-slip and reverse faulting regions. Corresponding focal plane mechanisms are shown to the right.

of density from the surface to the depth of interest, z . In other words,

$$S_v = \int_0^z \rho(z)g \, dz \approx \bar{\rho}gz \quad (5)$$

where $\rho(z)$ is the density as a function of depth, g is gravitational acceleration and $\bar{\rho}$ is mean overburden density. It is, of course, necessary to add atmospheric pressure and the pressure resulting from the weight of water at the Earth surface, as appropriate.

Second, the horizontal principal stresses are almost never equal and may be less than or greater than the vertical stress. In fact, the relative magnitudes of the principal stresses can be simply related to the faulting style currently active in a region. As illustrated in Figure 2 (and following Anderson, 1951), characterizing a region by normal, strike-slip or reverse faulting is equivalent to defining the horizontal principal stress magnitudes with respect to the vertical stress. When the vertical stress dominates in extensional deformational regions ($S_1 = S_v$), gravity drives normal faulting. Conversely, when both horizontal stresses exceed the vertical stress ($S_3 = S_v$) compressional deformation (shortening) is accommodated through reverse faulting. Strike-slip faulting represents an intermediate stress state ($S_2 = S_v$), where

the maximum horizontal stress is greater than the vertical stress and the minimum horizontal stress is less ($S_{Hmax} \geq S_v \geq S_{Hmin}$).

The concept of effective stress is used to incorporate the influence of pore pressure at depth where a component of effective stress σ_{ij} is related to the total stress S_{ij} via

$$\sigma_{ij} = (S_{ij} - \delta_{ij}P_p) \quad (6)$$

where δ_{ij} is the Kronecker delta and P_p is the pore pressure.

Laboratory studies of the frictional strength of faulted rock carried out over the past several decades indicates that the Coulomb criterion describes the frictional strength of faults. That is, fault slippage will occur when

$$\tau = S_0 + \mu\sigma_n \quad (7)$$

where τ is the shear stress acting on the fault, S_0 is the fault cohesion, μ is the coefficient of friction on the fault and σ_n is the effective normal stress acting on the fault plane. The maximum shear stress is given by $\frac{1}{2}(S_1 - S_3)$.

Using the concept of effective stress at depth, we can extend Anderson's faulting theory to predict stress magnitudes at depth through utilization of simplified 2D Mohr-Coulomb failure theory. 2D faulting theory assumes that failure is only a function of the difference between the last and greatest principal effective stresses σ_1 and σ_3 as given by Jaeger and Cook (1971)

$$\sigma_1/\sigma_3 = (S_1 - P_p)/(S_3 - P_p) = ((\mu^2 + 1)^{1/2} + \mu)^2 \quad (8)$$

Thus, a third point about crustal stress that can be derived from Andersonian faulting theory is that the magnitudes of the three principal stresses at any depth are limited by the strength of the Earth's crust at depth. In the case of normal faulting, stress magnitudes are controlled by σ_v , and σ_{Hmin} which correspond to σ_1 and σ_3 , respectively, and σ_{Hmax} corresponds to σ_2 which is intermediate in value between σ_v , and σ_{Hmin} and does not influence faulting. Coulomb failure theory indicates that frictional sliding occurs when the ratio shear stress to effective normal stress on preexisting fault planes is equal to the coefficient of friction. As the coefficient of friction is relatively well defined for most rocks and ranges between ~ 0.6 and 1.0 (Byerlee, 1978), Equation (8) demonstrates that frictional sliding will occur when $\sigma_1/\sigma_3 \sim 3.1$ – 5.8 . For the case of hydrostatic pore pressure, and commonly observed friction coefficients of 0.6 (e.g., Townend and Zoback, 2000), in extensional areas $S_{Hmin} \sim 0.6 S_v$, in reverse faulting areas $S_{Hmax} \sim 2.3 S_v$ and in strike-slip faulting areas [when $S_v \sim 1/2 (S_{Hmax} + S_{Hmin})$], $S_{Hmax} \sim 2.2 S_{Hmin}$. As discussed below, these simple relationships have been confirmed by *in situ* stress measurements to depths of almost 8 km at a number of sites in intraplate areas.

2. Indicators of Contemporary Stress

Information on the state of stress in the lithosphere comes from a variety of sources: earthquake focal plane mechanisms; young geologic data on fault slip and volcanic alignments; *in situ* stress measurements; and stress-induced wellbore breakouts and drilling-induced tensile fractures. A stress measurement quality criterion for different types of stress indicators was developed by Zoback and Zoback (1989, 1991). This quality criterion was subsequently utilized in the International Lithosphere Program's World Stress Map Project, a large collaborative effort of data compilation and analyses by over 40 scientists from 30 different countries (Zoback, 1992). A special issue of the *Journal of Geophysical Research* (vol. 97, pp. 11703–12014, 1992) summarized the overall results of this project as well as presented the individual contributions of many of these investigators in various regions of the world. Today, the World Stress Map (WSM) database has more than 9100 entries and is maintained at the Heidelberg Academy of Sciences and Humanities (Mueller *et al.*, 1997).

Zoback and Zoback (1991) discussed the rationale for the WSM quality criterion used in the World Stress Map project in detail. The success of the WSM project demonstrates that with careful attention to data quality, coherent stress patterns over large regions of the Earth can be mapped with reliability and interpreted with respect to large-scale lithospheric processes.

2.1 Earthquake Focal Mechanisms

Although earthquake focal plane mechanisms are the most ubiquitous indicator of stress in the lithosphere, determination of principal stress orientations and relative magnitudes from these mechanisms must be done with appreciable caution. The pattern of seismic radiation from the focus of an earthquake permits construction of earthquake focal mechanisms (right column of Fig. 2). Perhaps the most simple and straightforward information about *in situ* stress that is obtainable from focal mechanisms and *in situ* stress is that the type of earthquake (i.e., normal, strike-slip, or reverse faulting) defines the relative magnitudes of S_{Hmax} , S_{Hmin} and S_v . In addition, the orientation of the fault plane and auxiliary plane (which bound the compressional and extensional quadrants of the focal plane mechanism) define the orientation of the P (compressional), B (intermediate), and T (extensional) axes. These axes are sometimes incorrectly assumed to be the same as the orientation of S_1 , S_2 , and S_3 .

For cases in which laboratory-measured coefficients of fault friction of ~ 0.6 – 1.0 are applicable to the crust, there is a nontrivial error of ~ 15 – 20° if one uses the P , B , and T axes as approximations of average principal stress orientations, especially if the orientation of the fault plane upon which

the earthquake occurred is known (Raleigh *et al.*, 1972). If friction is negligible on the faults in question (but higher in surrounding rocks), there can be considerable difference between the P , B , and T axes and principal stress directions (McKenzie, 1969). An earthquake focal plane mechanism always has the P and T axes at 45° to the fault plane and the B axes in the plane of the fault. With a frictionless fault the seismic radiation pattern is controlled by the orientation of the fault plane and not the *in situ* stress field. One result of this is that just knowing the orientation of the P -axis of earthquakes along weak, plate-bounding strike-slip faults (like the San Andreas), does not allow principal stress orientations to be defined from the focal plane mechanisms of the strike-slip earthquakes occurring on the fault (Zoback *et al.*, 1987). For this reason, it is common practice to omit plate-boundary earthquakes from regional stress compilations (see below).

Principal stress directions can be determined directly from a group of earthquake focal mechanisms (or set of fault striae measurements) through use of inversion techniques that are based on the slip kinematics and the assumption that fault slip will always occur in the direction of maximum resolved shear stress on a fault plane (cf, Gephart and Forsyth, 1984; Michael, 1984; Angelier, 1990). Such inversions yield four parameters, the orientation of the three principal stress and the relative magnitude of the intermediate principal stress with respect to the maximum and minimum principal stress.

The analysis of seismic waves radiating from an earthquake can also be used to estimate the magnitude of stress released in an earthquake (stress drop), although not absolute stress levels (Brune, 1970). In general, stress drops of crustal earthquakes are on the order of 1–10 MPa (Hanks, 1977). Equation (8) can be used to show that such stress drops are only a small fraction of the shear stresses that actually causes fault slip if pore pressures are approximately hydrostatic at depth and Coulomb faulting theory (with laboratory-derived coefficients of friction) is applicable to faults *in situ*. This is discussed in more detail below.

2.2 Geologic Stress Indicators

There are two general types of *relatively young* geologic data that can be used for *in situ* stress determinations: (1) the orientation of igneous dikes or cinder cone alignments, both of which form in a plane normal to the least principal stress (Nakamura, 1977) and (2) fault slip data, particularly the inversion of sets of striae (i.e., slickensides) on faults as described above. Of course, the term *relatively young* is quite subjective but essentially means that the features in question are characteristic of the tectonic processes currently active in the region of question. In most cases, the WSM database utilizes data which are Quaternary in age, but in all areas represent the youngest episode of deformation in an area.

2.3 *In situ* Stress Measurements

Numerous techniques have been developed for measuring stress at depth. Amadei and Stephansson (1997) and Engelder (1993) discuss many of these stress measurement methods, most of which are used in mining and civil engineering. Because we are principally interested here in regional tectonic stresses (and their implications) and because there are a variety of nontectonic processes that affect *in situ* stresses near the Earth's surface (Engelder and Sbar, 1984), we do not utilize near-surface stress measurements in the WSM or regional tectonic stress compilations (these measurements are given the lowest quality in the criteria used by WSM as they are not believed to be reliably indicative of the regional stress). In general, we believe that only *in situ* stress measurements made at depths greater than 100 m are indicative of the tectonic stress field at midcrustal depths. This means that techniques utilized in wells and boreholes, which access the crust at appreciable depth, are especially useful for stress measurements.

When a well or borehole is drilled, the stresses that were previously supported by the exhumed material are transferred to the region surrounding the hole. The resultant stress concentration is well understood from elastic theory. Because this stress concentration amplifies the stress difference between far-field principal stresses by a factor of four, there are several other ways in which the stress concentration around boreholes can be exploited to help measure *in situ* stresses. The hydraulic fracturing technique (e.g., Haimson and Fairhurst, 1970; Zoback and Haimson, 1982) takes advantage of this stress concentration and, under ideal circumstances, enables stress magnitude and orientation measurements to be made to about 3 km depth (Baumgärtner *et al.*, 1990).

The most common methods of determining stress orientation from observations in wells and boreholes are stress-induced wellbore breakouts. Breakouts are related to a natural compressive failure process that occurs when the maximum hoop stress around the hole is large enough to exceed the strength of the rock. This causes the rock around a portion of the wellbore to fail in compression (Bell and Gough, 1979; Zoback *et al.*, 1985). For the simple case of a vertical well drilled when S_v is a principal stress, this leads to the occurrence of stress-induced borehole breakouts that form at the azimuth of the minimum horizontal compressive stress. Breakouts are an important source of crustal stress information because they are ubiquitous in oil and gas wells drilled around the world and because they also permit stress orientations to be determined over a great range of depth in an individual well. Detailed studies have shown that these orientations are quite uniform with depth, and independent of lithology and age (e.g., Castillo and Zoback, 1994).

Another form of naturally occurring wellbore failure is drilling-induced tensile fractures. These fractures form in the wall of the borehole at the azimuth of the maximum horizontal compressive stress when the circumferential stress acting

around the well locally goes into tension, they are not seen in core from the same depth (Moos and Zoback, 1990; Brudy and Zoback, 1993, 1999; Brudy *et al.*, 1997; Lund and Zoback, 1999; Wiprut and Zoback, 2000).

3. Distribution of Crustal Stresses

Color Plate 11 (top) shows maximum horizontal stress orientations for North America taken from the WSM database. The legend identifies the different types of stress indicators; because of the density of data, only the highest quality data are plotted (A and B quality, shown by lines of different length). The tectonic regime (i.e., normal faulting, strike-slip faulting or reverse faulting) where known is given by the symbol color. The data principally come from wellbore breakouts, earthquake focal mechanisms, *in situ* stress measurements greater than 100 m depth, and young (<2 My old) geologic indicators. These data, originally presented and described by Zoback and Zoback (1989, 1991), demonstrate that large regions of the North American continent (most of the region east of the Rocky Mountains) are characterized by relatively uniform horizontal stress orientations. Furthermore, where different types of stress orientation data are available (e.g., the eastern US), the correlation between the different types of stress indicators is quite good.

Two straightforward observations about crustal stress can be made by comparison of these different types of stress indicators. First, no major changes in the orientation of the crustal stress field occur between the upper 2–5 km, where essentially all of the wellbore breakout and stress measurement data come from, and 5–20 km where the majority of crustal earthquakes occur. Second, the criteria used to define reliable stress indicators appear to be approximately correct. In other words, data badly contaminated by nontectonic (near surface) sources of stress appear to have been effectively eliminated from the compilations.

4. First-Order Global Stress Patterns

Color Plate 12 shows global maximum horizontal compressive stress orientations based on the 1997 World Stress Map data base. As with Color Plate 11 (top), only data qualities A and B are shown and the symbols utilized in Color Plate 12 are the same as those in Color Plate 11 (top). Although global coverage is quite variable, the relative uniformity of stress orientation and relative magnitudes in different parts of the world is striking and permits mapping of regionally coherent stress fields. Color Plate 11 (bottom) presents a generalized version of the Global Stress Map that is quite similar to that presented by Zoback (1992) and shows, using large arrows, mean stress directions and stress

regime based on averages of clusters of data shown in Color Plate 12. Tectonic stress regimes are indicated in Color Plate 11 (bottom) by color and arrow type. Blue inward-pointing arrows indicate S_{Hmax} orientations in areas of compressional (strike-slip and thrust) stress regimes. Red outward-pointing arrows give S_{Hmin} orientations (extensions direction) in areas of normal faulting regimes. Regions dominated by strike-slip tectonics are distinguished with green thick inward-pointing and orthogonal, thin outward-pointing arrows. Overall, arrow sizes on Color Plate 11 (bottom) represent a subjective assessment of “quality” related to the degree of uniformity of stress orientation and also to the number and density of data.

A number of first-order patterns can be observed in Color Plates 11 (bottom) and 12:

1. In many regions a uniform stress field exists throughout the upper brittle crust as indicated by consistent orientations from the different techniques that sample very different rock volumes and depth ranges.
2. Intraplate regions are dominated by compression (thrust and strike-slip stress regimes) in which the maximum principal stress is horizontal.
3. Active extensional tectonism (normal faulting stress regimes) in which the maximum principal stress is vertical generally occurs in topographically high areas in both the continents and the oceans.
4. Regional consistency of both stress orientations and relative magnitudes permits the definition of broadscale regional stress provinces, many of which coincide with physiographic provinces, particularly in tectonically active regions. These provinces may have lateral dimensions on the order of 10^3 – 10^4 km, many times the typical lithosphere thickness of 100–300 km. These broad regions of the Earth’s crust subjected to uniform stress orientation or a uniform pattern of stress orientation (such as the radial pattern of stress orientations in China) are referred to as “first-order” stress provinces (Zoback, 1992).

5. Sources of Crustal Stress

As alluded to above, stresses in the lithosphere are of both tectonic and nontectonic, or local, origin. The regional uniformity of the stress fields observed in Color Plates 11 (top) and 12 argue for tectonic origins of stress at depth for most intraplate regions around the world. For many years, numerous workers suggested that residual stresses from past tectonic events may play an important role in defining the tectonic stress field (see discussion in Engelder, 1993). We have found no evidence for significant residual stresses at depth. If such stresses exist, they seem to be only important in the upper few meters or tens of meters of the crust where tectonic stresses are very small.

Similarly, no evidence has been found that indicates that horizontal principal stresses result simply from the weight of the overlying rock. This oversimplified theory is based on the “bilateral constraint,” the supposition that as a unit cube is stressed due to imposition of a vertical stress it cannot expand horizontally (because a neighboring unit cube would be attempting to expand in the opposite direction). If the bilateral constraint was applicable to the crust, the two horizontal principal stresses at depth would be equal and would always be less than the vertical stress (see Engelder, 1993). As demonstrated above, the dominance of compressional intraplate stress fields indicates that one, or both, horizontal stresses exceed the vertical stress. The broad regions of well-defined S_{Hmax} orientations are clear evidence of horizontal stress anisotropy. Thus, the predicted bilateral stress state is generally not found in the crust. In fact, the assumptions leading to the prediction of such a stress state are unjustified as the analysis assumes that an elastic crust exists in the absence of gravity (or any other forces) before gravity is instantaneously “switched” on.

In the sections below, the primary sources of tectonic stress are briefly discussed. Although it is theoretically possible to derive the significance of any particular source of stress, because the observed tectonic stress state is the result of superposition of a variety of forces acting on and within the lithosphere it is difficult to define the relative importance of any one stress source. This can only be resolved by utilizing careful modeling and well-constrained observations.

5.1 Plate Driving Stresses

Sources of the broadscale regions of uniform crustal stress that immediately come to mind are the same forces that drive (and resist) plate motions (e.g., Forsyth and Uyeda, 1975). A ridge push compressional force is associated with the excess elevation of the midocean ridges whereas the slab pull force results from the negative buoyancy of down-going slabs. Both of these sources contribute to plate motion and tend to act in the direction of plate motion. If there is flow in the upper asthenosphere, a positive drag force could be exerted on the lithosphere that would tend to drive plate motion, whereas if cold thick lithospheric roots (such as beneath cratons) may be subject to a resistive drag force that would act to inhibit plate motion. In either case the drag force would result in stresses being transferred up into the lithosphere from its base. There are also collisional resistance forces resulting either from the frictional resistance of a plate to subduction or from the collision of two continental plates. As oceanic plates subduct into the viscous lower mantle additional slab resistive forces add to the collision resistance forces acting at shallow depth. Another force resisting plate motion is that due to transform faults, although, as discussed below, the amount of transform resistance may be negligible. Finally, it has been proposed that a suction force may act on the overriding lithosphere in

a subduction zone. This force may tend to “suck” the overriding lithosphere toward the trench and result in back-arc spreading.

Although it is possible to specify the various stresses associated with plate movement, their relative and absolute importance in plate movement are not understood. Many researchers believe that either the ridge push or slab pull force is most important in causing plate motion, but it is not clear that these forces are easily separable or that plate motion can be ascribed to a single dominating force. This is discussed at some length by Richardson (1992) and has been addressed by a detailed series of finite element models of the stresses in the North American plate (Richardson and Reding, 1991).

5.2 Topography and Buoyancy Forces

Numerous workers have demonstrated that topography and its compensation at depth can generate sizable stresses capable of influencing the tectonic stress state and style (Frank, 1972; Artyushkov, 1973; Fleitout and Froidevaux, 1982; Sonder, 1990). Density anomalies within or just beneath the lithosphere constitute major sources of stress. The integral of anomalous density times depth [density moment of Fleitout and Froidevaux (1982)] characterizes the ability of density anomalies to influence the stress field and to induce deformation. In general, crustal thickening or lithospheric thinning (negative density anomalies) produces extensional stresses, whereas crustal thinning or lithospheric thickening (positive density anomalies) produces compressional stresses. In more complex cases the resultant state of stress in a region depends on the density moment integrated over the entire lithosphere. In a collisional orogeny, for example, where both the crust and mantle lid are thickened, the presence of the cold lithospheric root can overcome the extensional forces related to crustal thickening and maintain compression (Fleitout and Froidevaux, 1982).

5.3 Lithospheric Flexure

Loads on or within an elastic lithosphere cause deflection and induce flexural stresses which can be quite large (several hundred MPa) and can perturb the regional stress field with wavelengths as much as 1000 km (depending on the lateral extent of the load) (e.g., McNutt and Menard, 1982). Some potential sources of flexural stress influencing the regional stress field include: sediment loading, particularly along continental margins; glacial rebound; seamount loading; and the upwarping of oceanic lithosphere oceanward of the trench, the “outer arc bulge” (Hanks, 1971; Chapple and Forsyth, 1979). Sediment loads as thick as 10 km represent a potential significant stress on continental lithosphere (e.g., Turcotte *et al.*, 1977; Cloetingh *et al.*, 1982). Zoback (1992) suggested that a roughly 40° counterclockwise rotation of horizontal stresses on the continental shelf offshore of eastern Canada was due to

superposition of a margin-normal extensional stress derived from sediment load flexure.

6. The Critically Stressed Crust

Three independent lines of evidence indicate that intraplate continental crust is generally in a state of incipient, but slow, frictional faulting: (1) the widespread occurrence of seismicity induced by either reservoir impoundment [cf., fluid injection (cf. Healy *et al.*, 1968; Raleigh *et al.*, 1972; Pine *et al.*, 1983; Zoback and Harjes, 1997)]; (2) earthquakes triggered by small stress changes associated with other earthquakes (cf. Stein *et al.*, 1992, 1994, 1997); and (3) *in situ* stress measurements in deep wells and boreholes (cf. McGarr and Gay, 1978; Zoback and Healy, 1984, 1992; Brudy *et al.*, 1997; Lund and Zoback, 1999). The *in situ* stress measurements further demonstrate that the stress magnitudes derived from Coulomb failure theory utilizing laboratory-derived frictional coefficients of 0.6–1.0 predicts stresses that are consistent with measured stress magnitudes (Townend and Zoback, 2000). This is well-illustrated in Figure 3 by the stress data collected in the KTB borehole to ~8 km depth. Measured stresses are quite high and consistent with the frictional faulting theory [Eq. (7)]

FIGURE 3 Stress measurements in the KTB scientific research well indicate a “strong” crust, in a state of failure equilibrium as predicted by Coulomb theory and laboratory-derived coefficients of friction of 0.6–0.7 (after Zoback and Harjes, 1997).

FIGURE 4 Schematic diagram illustrating how the forces acting on the lithosphere keep the brittle crust in frictional equilibrium through creep in the lower crust and upper mantle (after Zoback and Townend, 2001).

with a frictional coefficient of ~ 0.7 (Brady *et al.*, 1997). A further demonstration of this “frictional failure” stress state was the fact that a series of earthquakes could be triggered at ~ 9 km depth in rock surrounding the KTB borehole by extremely low perturbations of the ambient, approximately hydrostatic pore pressure (Zoback and Harjes, 1997).

That the state of stress in the crust is generally in a state of incipient frictional failure might seem surprising, especially for relatively stable intraplate areas. However, a reason for this can be easily visualized in terms of a simple diagram as shown in Figure 4. The lithosphere as a whole (shown simply in Fig. 4 as three distinct layers: the brittle upper crust, the ductile lower crust and the ductile uppermost mantle) must support plate-driving forces. Figure 4 indicates a power-law creep law (e.g., Brace and Kohlstedt, 1980) typically used to characterize the ductile deformation of the lower crust and upper mantle. Because the applied force to the lithosphere will result in steady-state creep in the lower crust and upper mantle, as long as the “three-layer” lithosphere is coupled, stress will build up in the upper brittle layer due to the creep deformation in the layers below. Stress in the upper crust builds over time, eventually to the point of failure. The fact that intraplate earthquakes are relatively infrequent simply means that the ductile strain rate is low in the lower crust and upper mantle. Zoback and Townend (2001) discuss the fact that at the relatively low strain rates characterizing intraplate regions, sufficient plate-driving force is available to maintain a “strong” brittle crust in a state of frictional failure equilibrium.

Although there is appreciable evidence to suggest that the Coulomb criterion and laboratory-derived coefficients of friction are applicable to plate interiors, major plate boundary faults such as the San Andreas fault (and other plate-bounding faults) appear to slip at very low levels of shear stress. Appreciable heat flow data collected in the vicinity of the San Andreas show no evidence of frictionally generated heat (cf, Lachenbruch and Sass, 1980, 1992). This appears to limit average shear stresses acting on the fault to depths of ~ 15 km

to about 20 MPa, approximately a factor of 5 below the stress levels predicted by the Coulomb criterion assuming that hydrostatic pore pressure and laboratory-derived friction coefficients are applicable to the fault at depth. Zoback *et al.* (1987), Mount and Suppe (1987, 1992) and Townend and Zoback (2000) present evidence that the direction of maximum horizontal stress in the crust adjacent to the San Andreas is at an extremely high angle to fault plane. Like the heat flow data, the stress orientation data imply low resolved shear stresses on the fault at depth. Thus, it appears that the frictional strength of plate boundary faults is distinctly lower than intraplate faults which thus enables them to accommodate hundreds of kilometers of relative fault offset and correspondingly high strains.

7. Summary

Large portions of intraplate regions (lateral dimensions of 10^3 – 10^4 km) are characterized by relatively uniform stress fields suggesting that the state of stress in the brittle upper crust is dominated by large-scale tectonic processes. In general, principal stresses in the crust are in vertical and horizontal planes. In intraplate areas, *in situ* stress measurements and inferences based on topography and flexure all suggest that shear stresses in the upper lithosphere are fairly large and seem controlled by the frictional strength of the faulted crust. Unlike the interiors of plates, plate boundary faults (like the San Andreas fault and subduction zones) appear to be quite weak and slip at low levels of shear stress. At sufficient depth below the brittle upper lithosphere, stresses are likely controlled by the ductile flow properties of the constituent rocks and minerals. Plate driving forces are sufficient in magnitude to maintain the intraplate lithosphere in a state of frictional failure. This frictional failure is manifest as slow, steady-state creep deformation in the lower crust and upper mantle and brittle deformation in the upper crust.

Strength and Energetics of Active Fault Zones

James N. Brune

University of Nevada, Reno, USA

Wayne Thatcher

US Geological Survey, Menlo Park, USA

1. Introduction

The strength of active fault zones, i.e., the shear stress level required to cause fault slip, is fundamental to understanding the physics of earthquakes and to assessing earthquake hazard. Although many researchers have concluded that fault zones are weak (shear stresses 10 MPa or less averaged between 0 and ~20 km depth), others maintain that faults are strong (~100 MPa average of an approximate linear increase with depth). Thus, despite 30 y of dedicated research, relevant data remain inconclusive and fault strength remains uncertain by an order of magnitude. In part, this is because the main source of energy release in earthquakes is at depths greater than 5 km, inaccessible to direct instrumental observation. Very large earthquakes rupture to the Earth's surface where direct observation of the shallow rupture process is possible. However, the rupture characteristics at shallow depth may differ from those at seismogenic depths. To date no great ($M \geq 7.75$) earthquakes have occurred within a network of modern strong-motion instruments, but the large, well-recorded 1999 earthquakes in Turkey and Taiwan, both $M = 7.6$, show that this data gap is rapidly being filled. Furthermore, shear stress changes at the earthquake source (and the resulting seismic waves) are nearly linear perturbations of the absolute stress field. Thus, an unknown absolute background stress does not greatly affect the basic characteristics of the observed low frequency seismic waves and the observed geodetic deformation. Other, less-direct data must then be used to infer the physical state and ambient stress levels on active faults.

This chapter discusses available evidence and current ideas about fault zone strength and energetics. In our review we begin by outlining the general physical conditions prevailing in the Earth around active faults and summarize the generally agreed upon observational features of faulting and earthquake occurrence (Section 2). In doing so we make as few

assumptions as possible, because making uncertain assumptions may lead to logical inconsistencies and apparent paradoxes. For example, the absence of a measurable, frictionally generated heat flow anomaly near active faults, the so-called stress-heat flow paradox, rests upon assumptions that must somehow be incorrect. We wish to avoid such inconsistencies and to begin we introduce the observations and briefly state what they imply about fault zones. Subsequently, in Sections 3–8, we place these observations in an interpretative context and show how they have been used to infer various measures of fault shear stress. Section 9 summarizes our assessment of the average shear stress state near faults, argues for the general importance of stress heterogeneity in faulting processes, and discusses its implications.

2. General Physical Problem and Observational Constraints

Active faults are stressed by forces applied in the adjacent lithosphere, forces applied at or near plate boundaries due to the motions of the plates as well as those caused by lateral density contrasts within the lithosphere. Parts of some active faults, particularly those at major plate boundaries, slip aseismically, keeping fault zone shear stresses at about the same levels. Others slip primarily in earthquakes, with the fault shear stresses increasing between events and decreasing abruptly when sudden seismic slip occurs. During earthquakes, energy released at depth in the Earth propagates as elastic waves that cause ground shaking when they reach the Earth's surface. We have no direct access to the depths at which the major energy is released. Thus the physical processes must be inferred indirectly from evidence obtained at the surface (proposals for deep drilling into active crustal fault zones are pending, and

would provide the first direct evidence of the physical state at seismogenic depths). What we know about active faults and earthquakes thus comes from measurements made at or near the Earth's surface, and relies on seismology, structural geology, geodesy, and other geophysical data to infer the processes that are thus far inaccessible to direct observation. Studies of these data have established the following general features of stress, faulting, and earthquake occurrence. Detailed discussion follows in the section indicated.

1. Lateral density gradients in the lithosphere and variations in surface and sea-floor topography generate differential stresses of ~ 10 – 100 MPa available to drive slip on faults (Section 3).
2. Stresses measured *in situ*, in mines to depths of ~ 3 km and in boreholes to as deep as 9 km, are consistent with an approximately linear increase in shearing stress with depth of ~ 5 – 15 MPa km $^{-1}$. However, these measurements, particularly those below a few km depths, come from tectonically inactive plate interiors far from large active faults (Section 5).
3. Studies of inactive fault zones exhumed by erosion from seismogenic depths show them to be generally planar features, often with zones of crushed and comminuted rock (fault gouge, microbreccia, and cataclasite) up to 1 km in width. Faulting involves frictional slip to depths corresponding to temperatures of $\sim 350^\circ\text{C}$; at greater temperatures, deformation is primarily ductile, though still confined to relatively narrow shear zones (see Chapter 29 by Sibson). The fault zones show evidence of having been fluid saturated throughout their depth range (Section 5).
4. Heat flow measurements near active faults show no evidence for the heat generation expected if there were significant frictional resistance to fault slip. Furthermore, the orientations of principal compressive stresses near some major active faults are nearly normal to their strike. These two observations have been used to suggest faults are weaker (support less shearing stress) than the surrounding blocks, with an upper bound on average fault zone shear stress of ~ 20 MPa or less (Section 6).
5. Data from seismology, geodesy, and geological mapping of earthquake faulting are all consistent with average earthquake stress drops of ~ 0.1 – 10 MPa. These same data show, however, that slippage on the fault surface is very spatially heterogeneous, indicating local stress drops up to an order of magnitude greater than the average values (Section 7).
6. Measurements of strong ground motions made near earthquakes as large as $M7$ reveal accelerations as large as $1g$ and velocities up to 2 m sec^{-1} , indicating dynamic stress changes of about 30 MPa on the fault (Section 8).

In what follows we amplify on these observations and explain the inferences derived from them. In each case we point out the assumptions implicit in the inference, our own assessment of their reliability, and the implications of the results for fault zone stress and energetics.

3. External Stresses Available to Drive Faulting

The energy that drives active faulting ultimately comes from the stresses imposed on the lithosphere by the forces that drive and resist motions of the major plates and by stresses due to lateral density gradients in the lithosphere. Although at least eight different plate forces are potentially important, only some of these are believed to be decisive in determining the force balance (Forsyth and Uyeda, 1975) and hence the intraplate stress field (Zoback *et al.*, 1989). Here we shall describe only those considered in recent work. The forces are illustrated in Figure 1, which should be referred to in the subsequent discussion of each force.

The best understood force is the “ridge push,” F_{rp} , the mean excess pressure (differential stress) ΔP exerted on the lithosphere due to the elevation of the mid-ocean ridges above the surrounding sea floor. It is given by $\Delta P = 0.5g(\rho_a - \rho_w)e$, where g is the acceleration of gravity, ρ_a is the asthenospheric density, ρ_w is the density of sea water and e is the elevation of the ridge above the sea floor. All of these parameters are known rather well, and so the resulting differential stress estimate of 30 MPa averaged over an oceanic lithospheric thickness of ~ 70 km is probably accurate. Several recent studies suggest that the ridge push force is the most important determinant of intraplate stress in the North American plate (e.g., Richardson and Reding, 1991; Zoback, 1992). If so, the field has a particularly simple, predictable form and its magnitude is

FIGURE 1 Plate driving and resisting forces (modified from Forsyth and Uyeda, 1975). F_{TR} = transform fault resistance; F_{DF} = plate drag force; F_{CR} = plate drag under continents; F_{RP} = ridge push; F_{SP} = slab pull; F_{SR} = slab resistance.

bounded rather well. Since the load-bearing thickness of the continental lithosphere may well be considerably less than 70 km in active regions, differential driving stresses from ridge push could be as much as ~ 100 MPa in these areas.

The “slab pull” force, F_{sp} , is caused by the excess density of the cold subducting oceanic slab as it sinks into the hotter, more buoyant asthenosphere. Its magnitude can be estimated from the thermal structure of the descending plate (McKenzie, 1969) and it is likely to be the largest of the driving forces. The corresponding force per unit area acting on the lithosphere is about 180 MPa, but this is an upper bound estimate of the differential driving stresses imposed on the lithosphere by subduction. Slab descent into the mantle is almost certainly resisted by poorly known forces of comparable magnitude, F_{sr} in the asthenosphere, and F_{cr} on the intraplate interface of the subduction thrust. As a result, the net drive or resistance from subduction is not well known, although it is likely that this net force importantly influences differential stresses in some plates.

Transform fault resistance, F_{tf} , opposes the strike-slip motion of the plates on both oceanic transforms and continental transcurrent faults like the San Andreas system. Although these frictional and ductile resisting shear stresses could be significant, their magnitudes are poorly known. We discuss them further below in connection with lithospheric rheology. Quasi-static frictional shear resistance on the seismogenic upper crustal faults could average 60 MPa across strike-slip faults and as much as 400 MPa across the deeper portions of subduction thrusts (F_{cr} of Fig. 1). However, as discussed below, heat flow data in both transform and subduction settings place much lower thresholds on the magnitudes of these resisting shear stresses.

Finally, shear stresses imposed on the base of the lithosphere, either as driving or resisting forces, F_{df} , are potentially important but poorly known. F_{df} is a driving force if imposed by general convective flow of the mantle, or resistive if caused by the drag of the plates over a passive asthenosphere. Driving or resisting shear stresses of only a few bars integrated over the large basal area of the plates would have important influences on the intraplate stress field.

Whatever the magnitudes of these largely unknown forces their net effect is to impose a long-wavelength stress field on the interiors of the plates. It is this field, often modified by local perturbations, that supplies the “tectonic” shear stresses that drive active faulting.

Buoyancy forces caused by lateral density contrasts in crust or mantle are the most important local perturbations. Just as the elevated topography at midocean ridges leads to large intraplate stresses, a similar process occurs when elevated topography is caused by thickened continental crust. By considering the force balance for two columns of continental crust, one with thickness y_{cco} and the other thickened so that it has an additional elevation h , and assuming the two columns

are in isostatic balance, Turcotte (1982) showed the net horizontal force F_r is

$$F_r = \rho_c g h \left[y_{cco} + \frac{\rho_m h}{\rho_m - \rho_c} \right]$$

where ρ_c and ρ_m are the densities of crust and mantle respectively. If $y_{cco} = 35$ km, $\rho_m = 3300 \text{ kg m}^{-3}$, $\rho_c = 2750 \text{ kg m}^{-3}$ and we assume F_r is supported over an elastic crust 50 km thick, then we can obtain the resulting compressive stress as a function of elevated topographic height h . If $h > 3$ km then differential stresses exceed 100 MPa. In the absence of any other applied forces we expect these topographic effects will lead to extensional stresses within the elevated region and compressive stresses in the adjacent thinner crust. The same general principles that we have discussed for the crust apply to lateral density gradients in the mantle (see Fleitout and Froidevaux, 1982 for a general formulation), and both lead to stresses that can drive faulting.

3.1 Assessment

Our assessment is that intraplate differential stresses due to plate motion forces and lateral density gradients within the lithosphere can be estimated approximately and lie in the range ~ 10 – 100 MPa averaged over the entire lithosphere. They thus provide rough bounds on the magnitude of the long wavelength, far field shear stress that causes faulting.

4. Internal Fault Zone Stress and Energy Balance for Fault Slip

The tectonic stresses discussed above, supported by the lithosphere over long time intervals, provide the boundary stresses which ultimately supply energy for earthquakes and fault slip. Earthquake occurrence modulates the local stress field in an intermittent fashion while steady-state aseismic slip keeps shear stress at about the same level at all times. The fault zone (including gouge) represents an internal boundary on which we seek to infer the stresses. Relatively rapid earthquake fault slip will decrease stress on the fault and its surroundings, radiating seismic waves. In the process, work is done against frictional stresses that resist fault motions. Elastic stress accumulation subsequently restores the stress slowly, over hundreds or thousands of years, to an ambient prefailure level that represents the actual “strength” of the fault. The earthquake stress drop and the absolute ambient pre-earthquake stress, along with the frictional resisting forces active during sliding, determine the partitioning of stored elastic energy released during faulting (E) into seismic waves (E_s) and work done against resisting stresses (E_r). In what follows we outline how this partitioning provides a framework for considering

constraints on the magnitudes of stresses acting before, during and immediately after earthquake fault slip. This will in turn provide a bounding framework for evaluating various models and inferences of stress state.

To begin we discuss a relatively small rupture surface over which it may be assumed that the stress is uniform. We assume a confined planar fault surface and uniform stresses and stress changes over the fault. We define u as the total slip averaged over the fault area A . τ_i and τ_f are the initial and final shear stresses on the fault, and the average resisting shearing stress during slip is τ_r . Following Brune (1976) and Lachenbruch and Sass (1980), Figure 2 shows three possibilities for the relative magnitudes of the final stress and average resisting stress ($\tau_r > \tau_f$, overshoot; $\tau_r = \tau_f$, null; and $\tau_r < \tau_f$, locking). The total elastic energy release is the area under the straight line joining τ_i and τ_f in Figure 2,

$$E = \frac{1}{2}(\tau_i + \tau_f)uA \quad (1)$$

Then the work done against resisting stresses is the area under the line $\tau = \tau_r$ in Figure 2,

$$E_r = \tau_r uA \quad (2)$$

The seismically radiated energy is the difference between Eq. (1) and Eq. (2), the area between the elastic energy release line and the resisting stress line τ_r ,

$$E_s = E - E_r = \left[\frac{1}{2}(\tau_i + \tau_f) - \tau_r \right] uA \quad (3)$$

Figure 2 graphically shows how the energy partitioning depends on the relative magnitudes of the initial, final, and

FIGURE 2 Average stress levels during fault slip. Initial stress = τ_i , final stress = τ_f , resisting stress = τ_r , apparent stress = τ_a , stress drop = $\Delta\sigma$. Dashed line shows case of variable dynamic friction during slip. Three possibilities for the relative magnitudes of the final stress and average resisting stress are shown ($\tau_r > \tau_f$, overshoot; $\tau_r = \tau_f$, null; and $\tau_r < \tau_f$, locking).

resisting stresses on the fault. The detailed dynamics of earthquake faulting certainly depend on dynamic shear resistance, as shown by the dashed line in Figure 2, but average values remain useful for intuitive understanding.

We may relate several spatially averaged measures of stress by using Eqs. (1–3) and defining some commonly used stress parameters as follows

$$\text{Average loading stress: } \tau_e = \frac{1}{2}(\tau_i + \tau_f) \quad (4)$$

$$\text{Apparent stress: } \tau_a = \frac{1}{2}(\tau_i + \tau_f) - \tau_r \quad (5)$$

$$\text{Stress drop: } \Delta\sigma = \tau_i - \tau_f \quad (6)$$

Then since $E = E_s + E_r$ we have

$$\tau_e = \tau_a + \tau_r \quad (7)$$

Using Eqs. (5) and (6) we finally obtain

$$\tau_i = \tau_a + \frac{1}{2}\Delta\sigma + \tau_r \quad (8)$$

Equation (8) is useful because it relates stress measures that we can estimate with varying degrees of precision and uncertainty from observational data, permitting inter-comparisons and checks on consistency. In what follows we will critically assess the state of knowledge of each stress measure in order to constrain the true strength and energy balance in active fault zones. Our general objective is to understand what physical factors control stresses, to evaluate observations that constrain their magnitudes, and to assess whether these average stresses are relatively high (~ 100 MPa or greater) or rather low (~ 20 MPa or less). As we discussed previously, rough bounds can be placed on the initial stress τ_i based on intraplate stress estimates. The apparent stress τ_a can be obtained for individual earthquakes by seismically measuring the moment and radiated energy release. Stress drops ($\Delta\sigma$) for individual earthquakes can be estimated from geodetic measurements, as well as seismically. Stresses τ_r that resist fault motions generate heat, and thermal measurements near active faults constrain the long-term (millions of years) average resisting stress across crustal faults.

5. Quasi-static Lithospheric Rheology

The rheology of the lithosphere, the constitutive laws that determine quasi-static deformation for given applied stresses, may play a decisive role in governing the magnitude and distribution of ambient stress. It is the shear stress component of the ambient field resolved onto the fault that is identified with the initial stress τ_i in the quasi-static model for rupture discussed above. The upper 10–30 km of the crust, where ruptures typically nucleate and propagate, deforms elastically

or through brittle failure. Below these depths, aseismic fault slip and distributed bulk ductile deformation occur in the deeper portions of a lithospheric column that may be as much as ~ 100 km thick (Brace and Kohlstedt, 1980).

The vertical stratification and lateral heterogeneity of lithospheric rheology determine the coupling between the far-field tectonic stress, discussed above, and the local deformation. This variability in rheology affects the ways in which stresses are transferred into the “earthquake machine” in the seismogenic upper crust. Local changes in bulk lithospheric rheology, for example near major faults, could profoundly influence both the stress field and the patterns of active faulting.

The rheological behavior of fault zones, either during earthquake slip or quasi-static slip, is not yet well understood, and in what follows we use extrapolations from laboratory rock mechanics experiments to derive idealized static strength versus depth profiles for the lithosphere. It is not yet certain how far they can be applied to conditions existing in and near active faults. Indeed, as we shall see, observations from the San Andreas fault and elsewhere violate the simplest expectations based on these derived static strength profiles, and so additional complexities are needed to rationalize the field measurements within the rock mechanics framework. In addition, the stress field during faulting in the seismogenic upper crust may be dominated by dynamical effects that are not closely linked to the quasi-static, prefailure stress levels. Thus, although significant uncertainties also exist in understanding the rheology of the deeper, ductile lithosphere, the quasi-static parameters based upon laboratory experiments may more nearly apply there.

Whatever the actual stress state in the Earth, the conventional rock mechanics framework developed here is a useful standard against which to evaluate observations and models of fault zone strength. In what follows we separately consider the rheology of the seismogenic crust and the region that lies beneath it.

5.1 Brittle Upper Crust

Let us define strength as the maximum shear stress that can be supported by rocks. Within the conventional framework, in the upper 10–30 km of the Earth this strength is determined by the stresses required to cause frictional sliding on preexisting faults or fractures. For intact rock masses the brittle fracture strength is generally higher but is more difficult to estimate because it varies widely with rock type, temperature, and strain rate and it is not considered further here.

The general form of the failure condition for frictional slip is given by

$$\tau = \mu(\sigma_n - P) + \tau_0 \quad (9)$$

where τ and σ_n are the shear and normal stresses across a planar fault surface, μ is the coefficient of static friction on the surface,

P is the ambient fluid pressure, and τ_0 is a cohesion term which we subsequently drop for simplicity. Note that high fluid pressure P could considerably reduce the tectonic shear stress τ required to cause frictional failure, a point we will return to in Section 9.

Laboratory measurements of frictional sliding on rock surfaces under the temperature and pressure conditions of the crust provide potentially strong constraints on frictional slip. They lead to the important generalization that the frictional resistance to sliding is (with a few exceptions) independent of rock type and depends only upon confining pressure (Byerlee, 1978). All of the data except those for a few clay-rich minerals can be fit well assuming

$$\mu = 0.75 \quad (10)$$

5.1.1 Triaxial Stress State

If we consider a triaxial stress state with effective principal compressive stresses $(\sigma_1 - P) > (\sigma_2 - P) > (\sigma_3 - P)$ and the fault plane lying at angle θ to the σ_1 axis (Fig. 3), we may rewrite Eq. (9) in terms of the principal effective stresses (see Jaeger and Cook, 1976, p.14) $(\sigma_1' - \sigma_3') \sin 2\theta = \mu[(\sigma_1' + \sigma_3') - (\sigma_1' - \sigma_3') \cos 2\theta]$, where we have replaced all $(\sigma_i - P)$ by σ_i' . After a little algebra we obtain

$$\sigma_1' / \sigma_3' = (1 + \mu \cot \theta) / (1 - \mu \tan \theta) \quad (11)$$

This ratio has a minimum value for fault planes perpendicular to the $\sigma_1 - \sigma_3$ plane intersecting the σ_2 axis and oriented at angles of θ_0 to σ_1 . This angle is given by

$$\theta_0 = 45^\circ - \frac{1}{2} \tan^{-1} \mu = \frac{1}{2} \tan^{-1} (1/\mu) \quad (12)$$

Faults at this optimal orientation thus slip at the minimum value of σ_1' / σ_3' and it is often assumed that such faults exist in the crust when calculating its frictional strength. However, it is not uncommon for pre-existing faults not optimally oriented in this way to be reactivated in the current (different) tectonic stress field, in which case the stress ratio must be greater. Frictional lock-up occurs for faults oriented more than $2\theta_0$ from the σ_1 -axis (Fig. 3c), which defines the asymptotic limits for θ (Sibson, 1985). If all available orientations for pre-existing faults lie close to the $2\theta_0$ limit, new faults of optimum orientation may be formed at lower stresses by fracture of previously unfaulted rock.

In principle, failure could occur for $\theta > 2\theta_0$ but this would require negative values of the stress ratio σ_1' / σ_3' . This implies the effective least principal stress $\sigma_3' < 0$, i.e., $P > \sigma_3$, and the rock mass surrounding the fault may show evidence of tensional failure by hydraulic fracturing (see Chapter 29 by Sibson). This condition may apply without pervasive hydrofracture if the region of high pore pressure is confined near the fault zone, permitting slip at low effective stresses on very misoriented faults in a stress field characterized by locally

FIGURE 3 2D Mohr-Coulomb faulting theory. (a) Possible fault planes under triaxial stress state ($\sigma_1 > \sigma_2 > \sigma_3$). (b) Optimum failure planes as given by Eq. (12) in the text. (c) Frictional limits on fault plane orientation. Arrows show orientations of maximum (σ_1) and minimum (σ_3) principal stresses. The intermediate principal stress axis (σ_2) lies on intersection of other two axes and is perpendicular to them. Conjugate planes with opposite senses of slip are shown in each case.

elevated principal stress magnitudes (Rice, 1992). It is also likely that if a fluid phase were present, hydrofracture would keep σ_3' from becoming negative, thereby limiting the ambient stress and promoting lockup.

If we assume the frictional faults are optimally oriented according to Eq. (12) and assume a value for the friction coefficient μ of 0.75 we may use Eq. (11) to relate the magnitudes of the maximum and minimum principal effective stresses. At frictional equilibrium we obtain

$$\sigma_1' = 4.0 \sigma_3' \quad (13)$$

5.1.2 Andersonian Faulting Types and Strength Versus Depth

In the Earth one of the principal stresses is usually assumed to be vertical. This condition must apply at the surface, where shear stresses vanish, and experimental data from mines and boreholes indicate it is a good generalization to at least 3 km depth (McGarr and Gay, 1978). Then, in the 2D faulting theory of Anderson (1951) the style of faulting depends upon which of the principal effective stresses is vertical. If the maximum effective principal stress σ_1' is vertical, the minimum σ_3' is horizontal and the failure planes are normal faults. When the minimum principal stress σ_3' is vertical, thrust faulting results. If the intermediate principal stress σ_2' is vertical, σ_1' and σ_3' are horizontal and faulting is strike slip.

Given this geometry of the principal stresses and assuming a value for the coefficient of friction, we can determine the

orientations of thrust, normal and strike-slip faults that will slip at the lowest differential stress ($\sigma_1' - \sigma_3'$). Assuming $\mu = 0.75$, Eq. (12) can be used to obtain $\theta_0 = 27^\circ$. Thus, optimally oriented thrusts will dip at 27° , normal faults at 63° , and strike-slip faults will be oriented 27° to the direction of maximum compression.

The vertical effective principal stress σ_v' can be estimated independently, permitting the other principal effective stress to be calculated from Eq. (13). σ_v' is simply given by the weight of the overburden reduced by the ambient pore pressure,

$$\sigma_v' = \rho g z - P \quad (14)$$

where ρ is the density of the overburden and z is depth. In a fluid-saturated crust it is often assumed that pores or cracks are interconnected and a part of the rock column is supported by the fluid pressure $P = \rho_w g z$, where $\rho_w = 1000 \text{ kg m}^{-3}$ is the fluid density. For $\rho = 2700 \text{ kg m}^{-3}$, the gradient of σ_v' is 26.5 MPa km^{-1} under dry conditions and 16.7 MPa km^{-1} if pore pressure is hydrostatic.

For each of the main faulting types we can thus use Eqs. (13) and (14) to compute the gradient in resisting shear stress $\tau = 0.5 (\sigma_1' - \sigma_3') \sin 2\theta_0$ on optimally oriented faults under hydrostatic and dry conditions.

Normal:

$$\sigma_1' = \sigma_v' \quad \text{Hydrostatic, dry gradients} = 5.0, 8.0 \text{ MPa km}^{-1} \quad (15a)$$

Strike slip:

$$\sigma_2' = \sigma_v' \quad \text{Hydrostatic, dry gradients} = 8.0, 12.7 \text{ MPa km}^{-1} \\ \text{(strike-slip case assumes } \sigma_v' = 0.5(\sigma_1' + \sigma_3') \text{)} \quad (15b)$$

Thrust:

$$\sigma_3' = \sigma_v' \quad \text{Hydrostatic, dry gradients} = 20.0, 31.8 \text{ MPa km}^{-1} \quad (15c)$$

For normal and strike-slip faults extending from the surface to 15 km depth, the average resisting stresses under hydrostatic conditions are thus 38 and 60 MPa. For a thrust fault extending to 30 km, a common earthquake nucleation depth in subduction zones, the corresponding average value is 300 MPa.

Recalling our previous discussion on plate driving and resisting forces, we see that if resisting stresses of this magnitude actually occur on plate boundary faults they will play an important role in determining the force balance of the plates and the intraplate “tectonic” stress field of the lithosphere. However, such high resisting stresses would lead to significant frictional heat generation. Section 6 shows how heat flow measurements sharply constrain the amounts of possible frictionally generated heat along both the San Andreas fault in California and on the Cascadia subduction megathrust offshore of Washington, Oregon, and British Columbia.

5.2 Lower Crust and Lithospheric Mantle Rheology

Above temperatures ranging from 300° to 450°C both laboratory results and field observations show that the rheological behavior of rocks alters drastically. Pressure-sensitive fracture strength and frictional fault slip yield to bulk ductile flow controlled by dislocation creep, a very temperature- and strain rate-sensitive process that is also very dependent on rock type. However, strength in the ductile field is largely independent of both lithostatic pressure and pore pressure. For this deformation mechanism, the strain rate $\dot{\epsilon}$ and differential stress $(\sigma_1 - \sigma_3)$ are related by an expression of the form

$$\dot{\epsilon} = A (\sigma_1 - \sigma_3)^n \exp[-Q/RT] \quad (16)$$

or equivalently

$$(\sigma_1 - \sigma_3) = (\dot{\epsilon}/A)^{1/n} \exp[Q/nRT] \quad (16a)$$

where A , n and Q are constants that depend on rock type, R is the universal gas constant ($8.316 \text{ J mol}^{-1} \text{ K}^{-1}$), and T is absolute temperature. For many rock types $n \sim 3$, implying $(\sigma_1 - \sigma_3)$ increases by a factor of 2 for each eightfold increase in strain rate. Since temperature normally increases with depth, Eq. (16a) shows that for each rock type $(\sigma_1 - \sigma_3)$ is greatest at

the shallowest depths for which the flow law applies and thereafter decreases exponentially with increasing depth.

The exponential dependence of differential stress on rock type and temperature demonstrates the great influence of these factors on ductile strength. For example, laboratory experiments on ductile flow of dry quartzite, representing quartz-rich crustal rocks, yield $Q = 190 \text{ KJ mol}^{-1}$, whereas similar results for olivine, an upper mantle constituent, give $Q = 520 \text{ KJ mol}^{-1}$. Thus at the same temperatures and strain rates the ductile strength of these two rock types will differ by many orders of magnitude and there may be a significant strength contrast between the lower crust and uppermost mantle in many regions. Similarly, a change of just 100° in temperature of the lower crust or upper mantle will change ductile strength by a factor of 10.

5.3 Composite Quasi-static Strength Profile

If we consider lithospheric rheology to be controlled only by the frictional and ductile processes discussed above, the strength envelope for the crust is then determined by the lowest shear stress at a given depth that satisfies Eq. (9) or Eq. (16a). The depth at which both are satisfied is called the brittle/ductile transition. This image of lithospheric strength is certainly oversimplified, because there is a significant depth range over which a transitional, semibrittle behavior is likely to be important (Kohlstedt *et al.*, 1995) and frictional (i.e., pressure-sensitive) stable sliding may well occur below the seismogenic zone. Recent work suggests that the sharp peak in strength predicted at the brittle–ductile transition (see Fig. 4) may be blunted and modestly decreased by semibrittle processes (e.g., Kohlstedt *et al.*, 1995, Fig. 7, 9). Although these complexities may be important in the earthquake nucleation process, they are likely to be confined to a small fraction of the crustal column and the simple partition into frictional and ductile domains remains useful and intuitively instructive (see also Chapter 29 by Sibson).

Figure 4 shows strength versus depth, plotted as $(\sigma_h - \sigma_v)$ for thrust and normal faulting. Dry and hydrostatic pore pressure gradients are shown for each frictional sliding case. Pore pressure is parameterized by λ the ratio of the pore pressure P to the total vertical stress σ_v . Ductile strength curves are shown for both dry quartzite and olivine, a strain rate of $10^{-15} \text{ sec}^{-1}$ and a geothermal gradient of 15° km^{-1} (appropriate for old oceanic lithosphere or stable continental interiors) are assumed.

What general conclusions can be drawn from composite strength profiles like Figure 4? Provided our assumptions that (1) upper crustal rocks are fractured and frictional resistance to slip on optimally oriented faults limits ambient stresses there, and (2) temperature-sensitive creep properties of rocks rich in quartz and olivine determine limiting stresses at greater depths, then lithospheric stresses will lie within the bounds shown in Figure 4. A region of high strength is then expected

FIGURE 4 Composite strength profile for the continental cratonic lithosphere. Difference between maximum and minimum horizontal and vertical stress versus depth. If λ = ratio of pore pressure to vertical (overburden) stress, dry corresponds to $\lambda = 0$ and hydrostatic to $\lambda = 0.37$. Both quartz and olivine rheologies are used for ductile lithosphere and assumed thermal gradient is 15°C km^{-1} . A strain rate of 10^{-15} s^{-1} is assumed.

in the midcrust, near the transition between the frictional and ductile fields, and possibly also in the uppermost mantle, where a compositional change from quartzo-feldspathic rocks to more basic, olivine-rich compositions is expected. Depending on many factors this region of high strength lies in the depth range 15–40 km, with much lower ambient values above and below this depth interval. Depending on composition, temperature, and to a lesser extent strain rate, it is also possible that the ductile lower crust has a lower strength than either the overlying crust or the underlying upper mantle. For example, the strength curve for quartz (QTZ) in Figure 4 shows a sharp decrease in the 15–20 km depth range that is caused by the normal increase in temperature with depth and the exponential dependence of differential stress on temperature in Eq. (16a). Therefore, in some regions ductile flow may be concentrated in this low strength layer. However, it should be noted that quartz content generally diminishes in the lower continental crust.

5.4 Observational Constraints on Quasi-static Strength Profile

Direct measurements of stress in active fault zones at seismogenic depths have not yet been made. For constraints we must presently rely largely on measurements in plate interiors and on indirect estimates based on the effects of fault zone stress. *In situ* horizontal stresses measured in deep level mines to depths of 3 km (McGarr and Gay, 1978) and from the KTB deep scientific borehole drilled to 8 km depth in Germany (Brudy *et al.*, 1997) are plotted versus depth in Figure 5. The results from the KTB hole in particular support the expectations

FIGURE 5 Observations of maximum and minimum horizontal *in situ* stress versus depth. Determinations are from mines in southern Africa at depths shallower than 2.5 km (McGarr and Gay, 1978) and from below 3 km in the KTB scientific borehole in southern Germany (Brudy *et al.*, 1997), both in stable continental interiors. The range of possible values from KTB are shown shaded.

based on the frictional strength profiles, and the gradient of horizontal differential stress of $14\text{--}19 \text{ MPa km}^{-1}$ (not shown) lies between the strike slip and thrust gradients for hydrostatic pore pressure.

The results of Figure 5 support the “rock mechanics” strength model for frictional slip in the regions sampled, but several indirect observations suggest major faults are considerably weaker. We discuss heat flow constraints in detail in the next section but first consider an independent measure of relative fault strength.

This indicator of fault strength, first suggested by Mount and Suppe (1987) and Zoback *et al.* (1987), is the orientation of maximum horizontal compressive stress direction inferred from earthquake fault plane solutions and borehole elongations in the blocks adjacent to major fault zones. As shown in Figure 3a and Eq. (12), the angle, θ , between fault strike and the σ_1 axis should be about 27° for an expected fault friction coefficient $\mu \sim 0.75$. However, near both major strike-slip faults and subduction zones $\theta \sim 50^\circ\text{--}90^\circ$, suggesting that the shear strength of these faults is much less than that of the adjacent crust (if the fault were a free surface, supporting no

shear stress, two principal stresses would lie in its plane and the third would be perpendicular to the fault). Detailed profiles of θ versus distance from the San Andreas fault recently obtained by Hardebeck and Hauksson (1999) from fault plane solutions show a minimum of $\theta \sim 45^\circ$ – 70° at the fault and generally support previous observations from strike slip faults and subduction zones. However, the results of Hardebeck and Hauksson also reveal considerable along-strike and strike-normal variability in southern California.

In a related observation, Thatcher and Hill (1991, 1995) have shown that M 5.8–7.3 normal faulting earthquakes have dips that are strongly clustered near 45° (see Chapter 29 by Sibson, Fig. 6). Anderson's faulting theory and Eq. (12) suggest values should be centered near 60° , and the lower value suggests low friction coefficient μ or high pore pressure (or both) in these normal fault zones.

5.4.1 Assessment

The results in Figure 5 indicate that for inactive plate interiors the rock mechanics strength profile applies, and the brittle upper crust supports substantial shear stress. However, horizontal compressive stress orientations show that major fault zones support considerably lower stress, and the clustering of normal fault dips near 45° suggests these faults may also be weak.

6. Heat Flow and Frictional Stresses Resisting Fault Motions at Major Plate Boundaries

As we discussed in Section 4, stresses that resist fault motions generate heat, and measurements of surface heat flux near active faults can thus be used to infer bounds on the magnitudes of these resisting stresses. Using Eq. (2) the rate of work Q done against resisting stress τ_r for average fault slip rate v is $\tau_r v$ per unit fault area, or

$$Q = \tau_r v \quad (17)$$

No significant heat sinks are known (see Lachenbruch and Sass, 1980, p. 6186 for one justification), so the thermal effects of dissipative heating could be substantial. For example if $\tau_r = 100$ MPa and $v = 30$ mm y^{-1} , then $Q = 96$ m Wm^{-2} . We will discuss below how such a thermal flux at depth is conducted to the Earth's surface, but clearly sources of this magnitude would contribute significantly to observed heat flow and might violate observational constraints. For example, typical surface heat flow values above subduction thrusts average only about 40 m Wm^{-2} (Hyndman and Wang, 1993), and in a 50–100 km wide region near the San Andreas fault are only 30–50 m Wm^{-2} above background levels (Lachenbruch and Sass, 1980).

6.1 Resisting Stresses on the San Andreas Fault

The vertical strike-slip geometry of the San Andreas fault makes it particularly straightforward to detect any surface heat flux due to dissipative heating at depth on the fault. About 100 heat flux measurements have been made by the US Geological Survey in the vicinity of the fault, and they provide a uniquely detailed picture of the thermal regime near a major active fault. The data possess considerable scatter. Nonetheless, they show a zone of high heat flux averaging ~ 80 m Wm^{-2} , called the Coast Range Anomaly (CRA) by Lachenbruch and Sass (1980). It is spread over a region 50–100 km wide spanning the San Andreas fault zone, and heat flux is 40–50 m Wm^{-2} above background values to the east.

An important feature of the data is that it applies to all of the San Andreas fault system from its inception at the Mendocino triple junction on the north to the “big bend” of the fault 700 km to the south. It thus includes both the seismogenic, predominantly locked segments of the northern San Andreas fault system, which has several active strands, and the central ~ 160 -km long creeping segment of the San Andreas, where nearly all of the motion currently occurs as aseismic slip on a single fault. In neither region is there any obvious local anomaly of the kind expected from dissipative heating on the upper crustal portions of the fault.

To understand the form of this expected thermal anomaly, consider the simple 2D model of dissipative heat generation on the fault shown in Figure 6a. For resisting stress τ_r and slip velocity v acting over depth range d , the rate of heat generation q per unit length of fault is given by

$$q = \tau_r v d \quad (18)$$

Provided the depth of this source, a , is large compared to its width d , following Brune *et al.* (1969) we may write the surface heat flux $Q_0(x, t)$ due to conductive heat transfer as a function of distance x from the fault and time since initiation of slip,

$$Q_0(x, t) = q/\pi[a/(a^2 + x^2)] \exp[-(a^2 + x^2)/4\kappa t] \quad (19)$$

where κ is the thermal diffusivity (10^{-6} m²s⁻¹).

Assume for the moment that the resisting stress increases roughly linearly with depth, as suggested by Figures 4 and 5, and is greatest near earthquake nucleation depths, about 10 km on the San Andreas fault. The time-dependent exponential term in Eq. (19) will then be negligible after a few million years of slip. The steady-state surface heat flux will have a maximum value $q/\pi a$ at the fault, decrease to half this value at $x = a$, and thereafter decrease rapidly with increasing distance. Therefore if we take $v = 30$ mm y^{-1} and $\tau_r = 80$ MPa acting over a depth range of 5 km centered at depth $a = 10$ km, we easily find that the maximum surface heat flow anomaly (i.e., excess over background) is 40 m Wm^{-2} and it decreases

FIGURE 6 (a) Model geometry for heat generation on a vertical strike-slip fault. Resisting stress σ acts on a fault strip of width d centered at depth a below the ground surface. (b) Heat flux versus distance from central San Andreas fault (data from Region 3 of Lachenbruch and Sass, 1980). Mean heat flux within about 40 km of the fault, 86 m W m^{-2} , is shown by dashed line. This “Coast Range Anomaly” (CRA) lies $40\text{--}50 \text{ m W m}^{-2}$ above background values ~ 100 km east of the San Andreas fault.

rapidly (with scale length a) away from the fault. No such local heat flow anomaly is observed in the data (Fig. 6b). Indeed, individual heat flow profiles across the fault, like that in Figure 6b, fail to show any anomaly larger than the noise in the data, $5\text{--}10 \text{ m W m}^{-2}$, so an upper bound on frictional resistance of about 10 MPa is indicated.

Assuming uniform or linearly increasing distributions of resisting stress with depth (Brune *et al.*, 1969; Lachenbruch and Sass, 1980) makes the analysis more precise. However, unless the dissipative heating is all concentrated below ~ 10 km depth, the resolvable features of the computed surface heat flow profile do not change and the main conclusion is unaltered. Average resisting stress on the seismogenic portion of the San Andreas fault is thus no greater than about 10 MPa, about a factor of five less than suggested by the extrapolation of laboratory-based estimates of frictional fault strength (Fig. 4).

If frictionally generated heat were concentrated at depths below 15 km, the anomaly at the surface would be considerably broadened, and less obvious. A possibility (Thatcher and England, 1998) is that the CRA (coast range anomaly), the regionally high heat flux in Figure 6b, is caused by

distributed shear heating due to ductile flow beneath the depths where frictional processes dominate. As the strength profiles of Figure 4 suggest, and Thatcher and England (1998) show, ductile shear heating is concentrated near the ductile strength maximum at the brittle–ductile transition. The resulting heat source thus behaves like a line source concentrated at this depth and its effects can be approximated well by Eq. (19). The surface heat flux distribution predicted by this model is relatively broad and decreases away from the fault with a scale length equal to the depth of the brittle–ductile transition. The ductile shear zone model can generally account for the main features of the CRA (see Thatcher and England, 1998, Figs. 14, 15, 16).

Another proposed explanation of the CRA is that it results from advective transfer of frictionally generated heat by fluid flow away from the fault (Hanks, 1977; Williams and Narasimhan, 1989; Scholz, 2000). In this hypothesis, resisting stresses on the fault could be as high as given in Eq. (15b), with the CRA being smeared out by convective flow of groundwater away from the fault.

6.2 Resisting Stresses on Subduction Thrusts

At subduction zones the geometry of faulting and several potential sources and sinks of heat influence the surface heat flux and affect our ability to distinguish effects of dissipative heating on the fault. These features have been considered in detail with sophisticated numerical models of heat conduction, but the essential features can be intuitively understood and resisting stresses bounded by a simple analytic model of the thermal regime presented by Molnar and England (1990).

Recall from frictional faulting theory that resisting stresses on thrusts could be *very* high (the shear stress gradient for hydrostatic pore pressure is $\sim 20 \text{ MPa km}^{-1}$, implying 600 MPa at 30 km depth!). If shear stress on subduction thrusts was this high it would strongly resist plate motions. Furthermore, the thermal effects of such dissipative heating would be enormous. For example, if $v = 40 \text{ mm y}^{-1}$ and resisting stress was even just half the value suggested by Andersonian faulting theory, then $Q \sim 400 \text{ m W m}^{-2}$ of fault surface! We will discuss below how such a thermal flux at depth would be conducted to the Earth’s surface, but clearly sources of this magnitude would significantly violate observed heat flow constraints. (Note that the heating required to generate arc magmas occurs 100–200 km farther landward and at depths of ~ 80 km in the slab.)

The geometry of the model is shown in Figure 7a. A plate with dip δ is subducting at velocity v . Its motion is resisted by shear stress τ_r , which may be a function of the depth to the fault plane Z_f . Three sources of heat are important in determining the temperature above the slab and conduction to the Earth’s surface: (1) resistive shear heating, as given by Eq. (17), acts on the subduction thrust; (2) the heat Q_o from the descending slab; and (3) heat generated by radiogenic decay in

FIGURE 7 (a) Geometry and heat sources of subduction thrust fault model. 1, Shear heating on interplate thrust; 2, heat from subducting oceanic slab; 3, heat from upper plate radiogenic decay. See text for definition of symbols. (b) Cascadia heat flux versus distance from trench axis compared with 1D model discussed in text and with 2D heat finite element model of Hyndman and Wang (1993).

the overlying plate. The advective downward transport of heat by the descending slab must be accounted for in deriving the effect of these three heat sources on the surface heat flux. However, Molnar and England have shown that for gentle slab dips ($\delta < 30^\circ$) it is possible to correct for this advection, ignore the effect of lateral heat conduction in the overlying plate, and obtain 1D analytic expressions for the temperature field. The heat flux at any point on the surface a distance Z_f above the slab is then given by

$$k \frac{dT}{dz} = \frac{\tau_r v}{S} + \frac{Q_o}{S} + A_o D [1 - e^{-Z_f/D}] \quad (20)$$

where the advective correction term, S , is

$$S = 1 + \sqrt{\frac{Z_f v \sin \delta}{\kappa}} \quad (21)$$

and κ is the thermal diffusivity. The last term in Eq. (20) represents the contribution to surface heat flux of radioactive heat production A_o that decreases exponentially with depth on a scale length D .

Using the Cascadia subduction zone as an example we can show that any contribution to surface heat flux from resistive shear heating must be quite small. The following parameters

are taken as representative for Cascadia (Hyndman and Wang, 1993):

Subduction velocity, $v = 45 \text{ mm y}^{-1}$

Fault dip, $\delta = 15^\circ$

Heat flux, Oceanic slab, $Q_o = 120 \text{ m W m}^{-2}$

Crustal radioactive concentration, $A_o = 0.6 \mu \text{ W m}^{-3}$

Decay depth, Crustal radioactivity, $D = 10 \text{ km}$

Thermal diffusivity, $\kappa = 10^{-6} \text{ m}^2 \text{ s}^{-1}$

Hyndman and Wang (1993) show that the surface heat flux at a distance $Z_f = 15 \text{ km}$ above the subducting Juan de Fuca slab is about 50 m W m^{-2} . For the parameters listed above the advective correction term $S = 3.3$ and the surface flux contribution from the slab is 36 m W m^{-2} and from crustal radioactivity is 6 m W m^{-2} . Thus the last two terms on the right-hand side of Eq. (20) account for most of the observed heat flux, leaving no more than about 8 m W m^{-2} to be allocated to shear strain heating. Clearly resisting stresses (either quasi-static or dynamic) on the Cascadia megathrust must be quite small. Figure 7b shows a sample comparison between model and data from southern Vancouver Island. For illustrative purposes we have taken a modest resisting stress gradient $\tau_r = 0.05 \rho g Z_f \text{ MPa}$, but this contributes no more than 10 m W m^{-2} to the surface heat flux. This figure shows that resisting stresses on the Cascadia megathrust are quite low and, as is the case for the San Andreas fault, any thermal contribution is not distinguishable above the noise levels of the heat flow data.

Similar results have been obtained in other subduction zones. Hyndman *et al.* (1995) use the extensive suite of heat-flow data from the Nankai Trough subduction zone of southwest Japan to demonstrate resisting stresses there are as low as in Cascadia. A synoptic review by Hyndman and Wang (1993) of heat-flow data from other circum-Pacific subduction zones suggests the same conclusion (see also Tichelaar and Ruff, 1993). In particular, in Northern Honshu, landward of a segment of the Japan Trench that is subducting predominantly aseismically (Pacheco *et al.*, 1993), no anomalous heat generation attributable to frictional resistance was observed.

6.3 Assessment

We suggest that the heat flux measurements from the San Andreas transform and the Cascadia subduction zone provide strong evidence that stresses resisting slip on major faults are relatively low, on average $\sim 20 \text{ MPa}$ or less on subduction thrusts and $\sim 10 \text{ MPa}$ or less on the San Andreas. Since this estimate is an average over the seismogenic fault plane, values at any point could be considerably higher (or lower) than this mean. In particular, these resisting stresses could locally be higher on the deeper portions of the fault, at the depths where most large and great earthquakes nucleate.

Despite suggestions that advective transport of frictionally generated heat away from active faults is a quantitatively

important process, the preponderance of evidence supports a conductive model of heat transfer near major faults. On the San Andreas fault the integrated heat energy represented by the CRA is about what would be generated by frictional heating on a fault stressed according to Eq. (15b). With a viable mechanism for distributing this locally generated heat across the California Coast Ranges, the CRA might be explained. Williams and Narasimhan (1989) suggest fluid flow induced by the hydraulic gradients due to high topography along parts of the San Andreas, but this mechanism would seem to apply only to restricted segments of the fault. Lachenbruch and Sass (1980, pp. 6196–6198) give qualitative arguments against vigorous hydrothermal circulation near the San Andreas, noting that the integrated output of thermal springs along the fault is orders of magnitude too small to be due to frictional heating from a fault obeying Eq. (15b). However, they do concede that heat transport at low flow rates and moderate temperatures could be significant but very difficult to detect. There is no regionally high heat flow above the upper ~40 km of subduction thrusts (see Fig. 7b). Thus, regardless of heat transfer mechanism, it seems difficult to argue for the frictional heat generation implied by Eq. (15c).

In several regions, the heat flow constraint on frictional resistance applies to major faults that currently slip aseismically. Although it is not possible to be certain that the current aseismic behavior is typical of long-term patterns, the similar behavior of seismogenic and creeping faults suggests the mechanism responsible for weakening these faults may operate for both quasi-static and dynamic slip.

The role of heat generation by ductile shearing is uncertain. Although this mechanism can account for the heat-flow patterns observed in California, the slab window model of Dickinson and Snyder (1979) is at least as successful. In this model, the Juan de Fuca slab north of the Mendocino triple junction is subducting at a shallow angle and the process of triple junction migration thus exposes hot upper mantle at the base of the crust adjacent to the newly created San Andreas fault. Lachenbruch and Sass (1980) showed that this model explains the heat flow data and also the age progression of young volcanics southeast of the Mendocino triple junction. In addition, it matches the observation that the CRA is not symmetrically centered on the San Andreas, as required by models (like ductile shearing) that localize heat sources on a single fault or its downward continuations. However, the extent and history of exposure of the slab window is uncertain, and this heating mechanism may not be generally applicable throughout California.

Ductile shearing has not yet been modeled in subduction settings. However, reference to the 1D model (Yuen *et al.*, 1978) and relevant heat flux data (Fig. 8) suggest the existence of ductile shear heating below ~40 km depth would be difficult to prove (or disprove) from surface measurements.

FIGURE 8 Stress drop versus seismic moment obtained from seismic data (modified from Kanamori and Heaton, 2000).

7. Static Stress Drop in Earthquakes

As mentioned in Section 3, observations of the average static stress change due to earthquake faulting supply one of the important stress measures needed to understand fault energetics. Geodetic and seismologic methods can be used to estimate this parameter and its variations with position on the earthquake rupture. The average shear stress drop is given by

$$\Delta\sigma = Gu/L \quad (22)$$

where G is an elastic rigidity modulus, u is fault slip and L is a fault dimension. For small and moderate magnitude earthquakes, $\Delta\sigma$ is measured using the amplitude spectra of seismic body waves (Brune, 1970). For larger events, $\Delta\sigma$ is obtained using independent estimates of earthquake rupture dimensions from aftershock zone size and seismic moment obtained from long period seismograms. Geodetic measurements can be used to measure the strain change (essentially u/L) near the fault rupture, which is typically about 10^{-4} . Multiplied by an elastic modulus typical for the Earth's upper crust (~30 GPa), Eq. (22) yields $\Delta\sigma \sim 3$ MPa.

Figure 8 shows average stress drop $\Delta\sigma$ over a wide range of earthquake moment M_0 and equivalent magnitude, M_W . This compilation shows that $\Delta\sigma$ ranges from about 0.1 to 10 MPa and is essentially independent of magnitude (the rather lower values at smaller magnitudes may indicate a bias related to attenuation of high frequency seismic waves; see Hanks, 1982). Figure 8 also shows that some values as high as 100 MPa are occasionally observed.

The stress drop values given in Figure 8 are averaged over the entire earthquake rupture. However, both seismological and geodetic methods can be used to infer the spatial

FIGURE 9 Slip distributions in (a) the 1906 $M=7.8$ San Francisco earthquake (Thatcher *et al.*, 1997) and (b) the 1940 $M=7.1$ Imperial Valley, California earthquake (King and Thatcher, 1998).

distribution of seismic slip and hence map static stress drop variations on the earthquake fault plane. Two examples, for the great $M=7.8$ 1906 San Andreas earthquake and the 1940 $M=7.1$ Imperial Valley earthquake, both strike-slip events with extensive surface faulting and measurements of surface fault offset, are plotted in Figure 9. Inevitable smoothing and nonuniqueness of the fine scale features of the derived slip distributions preclude estimation of the largest static stress changes on the fault plane. However, these results, as well as seismological determinations of slip distribution (e.g., Archuleta, 1984; Cohee and Beroza, 1994; Wald and Heaton, 1994) indicate considerable heterogeneity in stress drop on earthquake rupture planes.

7.1 Assessment

The results summarized in Figure 8 reliably bound average stress drop, which has a mean value of ~ 3 MPa and ranges from

0.1 to 10 MPa. However, the along-strike and depth variations of slip indicated by slip mappings like Figure 9 show that stress release is quite heterogeneous, with stress drop varying by at least a factor of 5 on the fault.

8. Dynamics of Earthquake Faulting

The occurrence of earthquakes is the result of sudden release of elastic stress stored in blocks adjacent to the fault, and while slip is in progress inertial forces are very large, probably considerably larger than the quasi-static surface forces (stresses) which initially led to rupture nucleation and fault failure. Thus we anticipate that understanding the dynamics of earthquake slip may be crucial to understanding fault energetics, and inferences drawn from quasi-static analyses and observations may be a poor guide to dynamic behavior.

Ideally, we would like to have a firm theoretical and observational accounting of the stress-slip time history at every point on the earthquake fault rupture. Our current knowledge base falls far short of this objective. Instead of comprehensive theoretical understanding we have idealized kinematic and dynamical models and experiments with analogue materials. Rather than spatially complete, broadband seismic records near the largest earthquakes that occur on major faults we have local, usually bandlimited recordings of small and moderate events and distant seismograms from great earthquakes. Here we summarize these data and the inferences based on them and assess what they reveal about dynamic rupture processes.

8.1 Near-field Seismologic Observations

Near-field seismic records (those obtained within a few fault dimensions) from earthquakes as large as $M \sim 7$ permit estimates of ground velocities and accelerations which can be related to local estimates of slip duration and stress changes occurring during slip on the fault. Velocities of 2 m sec^{-1} and accelerations of $1g$ have been observed. If we define dynamic stress drop as the difference between initial stress and average stress during fault slip, such velocities and accelerations imply dynamic stress drops of $\sim 20 \text{ MPa}$. It should be emphasized that these observations are relatively few, may be affected by focusing of energy in the direction of rupture propagation ("directivity"), source–receiver path effects, and local recording site conditions. The peak values obtained may well apply to only restricted parts of the fault rupture and may be biased by sampling relatively more thrust faulting earthquakes.

However, the occurrence of the 1999 $M_w = 7.6$ Chi-Chi (Taiwan) earthquake supplies a large new data set that will be very important in refining our views of earthquake dynamics. This event produced surface rupture over a 125 km-long fault with up to 8 m of reverse dip-slip motion. It was recorded by over 500 free-field strong-motion accelerographs, many of them located in the near field. Preliminary analysis of these records (Mori and Ma, 1999) shows ground velocities of $1\text{--}3 \text{ m sec}^{-1}$ near the fault, with clearly larger motions on the upper or hanging wall block of the fault (Ni *et al.*, 1999). These observations reinforce earlier field evidence from thrust faults showing motions larger than $1g$ and 1 m sec^{-1} on the shallow part of the hanging wall, with associated evidence of relatively low accelerations and velocities on the adjacent foot-wall (Allen *et al.*, 1998).

8.2 Estimates of Radiated Energy and Apparent Stress

Although observations of near-field waveforms are rare, more observations exist of total seismically radiated energy (E_s). Using measures of E_s along with seismic determinations of

moment (M_o), the apparent stress τ_a is given by

$$\tau_a = GE_s/M_o \quad (23)$$

In the past, accurate estimation of E_s and τ_a has been hampered by the limited frequency bandwidth of seismographs and the unknown effects of high frequency attenuation and scattering. During the past 15 years the first problem has been solved by the deployment of broadband digital seismographic networks both locally and worldwide. The second problem, unknown attenuation effects, may remain and appear as a high frequency saturation of corner frequency and marked dependence of stress drop on seismic moment, M_o (Hanks, 1982). However, this effect is expected to become less important for E_s estimates as earthquake size increases. This follows because the major contribution to radiated energy occurs at frequencies near the spectral corner frequency (Hanks and Wyss, 1972), which is inversely proportional to source dimension and so generally decreases with increasing magnitude. Above $M \sim 7$ or $M_o \sim 10^{19} \text{ Nm}$ this corner frequency is 0.1 Hz or less and uncertainties due to wave attenuation may be less important.

This contention is supported by the compilation of τ_a versus M_o shown in Color Plate 13. The corner frequency saturation effect at small M_o (Hanks, 1982) would lead to underestimation of the true E_s (and hence an underestimate of τ_a) that becomes smaller with increasing magnitude or moment. Such a bias would cause an apparent increase of τ_a with increasing M_o . This effect is clearly seen at the smaller moments for several of the data sets shown in Color Plate 13, but disappears above $M_o \sim 10^{18} \text{ Nm}$. The absence of any dependence of τ_a on M_o is very clear in the teleseismic data of Choy and Boatwright (1995), which show apparent stresses spanning their full range over moments varying from 10^{17} to $10^{20.5} \text{ Nm}$.

There is one observational bias that deserves mention. Some existing data suggest teleseismic estimates of radiated energy are significantly less than those based on limited near-field data, especially for thrust faults (e.g., Singh and Ordaz, 1994). More recently, analysis of the uniquely complete data for the 1999 Chi-Chi (Taiwan) earthquake by Ni *et al.* (1999) has confirmed this. They showed that teleseismic estimates E_s and τ_a determined by the method of Choy and Boatwright (1995) yielded an apparent stress value of 0.5 MPa while the near-field value was about 5.0 MPa . Because the near-field data from the 1999 earthquake records are so singular it is not possible to assess how general this bias may be. That the event occurred on a shallowly dipping thrust fault may be significant and is discussed further below. However, we do note that the apparent stress value for the 1999 earthquake lies within the range of values shown for large earthquakes in Color Plate 13. For these events τ_a is small, averaging $\sim 0.5 \text{ MPa}$ and ranging from 0.03 to 6.7 MPa .

8.3 Theoretical, Numerical and Analogue Dynamical Models

Dynamical simulations of earthquake rupture are considerably more complex and computationally demanding than kinematic modeling, and much yet remains to be learnt. Elastic dislocation theory is most commonly applied to modeling of earthquake waveforms. However, this approach is essentially kinematic and requires specification either of idealized point sources and rise times or adjustable rupture velocities and distributions of slip-time functions on the rupture surface (e.g., Archuleta, 1984; Cohee and Beroza, 1994; Wald and Heaton, 1994). Fully dynamical models are only now beginning to be applied to earthquake rupture (e.g., Boatwright and Cocco, 1996) and most commonly utilize slip-weakening rules developed for fault slip in rock mechanics laboratories (Dieterich, 1979; Ruina, 1983). Fully 3D models that treat both vertical and inclined faults and account for fault plane heterogeneity are just now being developed and applied to match observed strong motion data.

One simple theoretical result supported by laboratory analogue modeling deserves special note. Both theory and lab results suggest that dynamic fault slip is accompanied by fault opening at the rupture front. Comninou and Dundurs (1977) derived a steady-state rupture model with a fault-opening mode. Freund (1978) criticized this model, showing that the assumed singularities at the front and back of the rupture were physically unrealistic. However, more recently Adams (1999) has argued that the fault-opening mode can occur for different types of assumed singularities. In a related model, Andrews and Ben-Zion (1997) and Ben-Zion and Andrews (1998) have shown such fault opening is a general feature of rupture at the contact of two elastic half-spaces with differing elastic moduli.

Fault opening is commonly observed in laboratory physical analogue experiments. Anooshehpour and Brune (1994) observed a steady-state propagating rupture with fault opening in a foam rubber physical model with a rough fault between both dissimilar and identical media. Anooshehpour and Brune (1994) showed that this mode was associated with a strong reduction in the amount of frictional heat generation on the fault. The opening mode between identical media was evidently associated with asperity interactions that fed energy into the opening mode. Fault opening or nearly complete reduction in fault normal stress has also been observed in plastic models of slip between identical media (Brown, 1998; Bodin *et al.*, 1998; Bouissou *et al.*, 1998; Uenishi *et al.*, 1999).

Numerical models have also shown the existence of a fault-opening mode under some conditions. Mora and Place (1994) showed the existence of such a mode in a lattice numerical model with a rough interface. This mode disappears when the roughness is decreased to zero (Mora and Place, 1998; Shi *et al.*, 1998). Mora and Place (1999) have shown that introducing particles on the fault which are allowed to rotate dynamically might also reduce fault friction, in part by causing local fault opening.

For shallow thrusts, fault separation may be greatly enhanced. Brune (1996) observed strong fault opening in a foam rubber model of thrust faulting. The opening increased as the rupture approached the surface, resulting in a spectacular flip of the hanging wall tip of the fault at the surface as it detached from the foot-wall. The ground motions on the foot-wall were much less than those on the hanging wall ($\sim 1/5$), resulting in much less energy radiating downward (corresponding to teleseismic radiation in the Earth) compared to the energy trapped in the hanging wall (corresponding to energy typically recorded on near-field accelerograms). Shi *et al.* (1998) reproduced many of the features observed in the foam rubber model using a dynamic lattice numerical model. This asymmetry of ground motion between hanging-wall and foot-wall blocks is supported by seismic observations described above (Allen *et al.*, 1998) and could explain the difference between local and teleseismic energy estimates for the 1999 Chi-Chi (Taiwan) earthquake (Ni *et al.*, 1999).

8.4 Assessment

The dynamics of faulting are the least well understood aspect of fault mechanics. However, seismological observations are suggestive that *on average* the apparent stress, which is a measure of the dynamic stress during slip, is relatively small, averaging ~ 3 MPa, about the same magnitude as the average static stress drop. This estimate is very sensitive to the accuracy of seismic estimates of radiated energy, which are uncertain by at least a factor of 3 (H. Kanamori, personal communication, 1998).

Collectively, the studies cited above suggest that one of the possible aspects of rupture dynamics, dynamic fault opening or normal stress reduction, may play an important role in earthquake rupture and explain some of the more puzzling aspects of faulting.

9. Summary and Discussion

Although uncertainties and caveats leave room for doubts, the picture that emerges from our review is that plate interiors are strong, supporting shear stresses consistent with the frictional strength of rocks determined in the laboratory (see Townend and Zoback, 2000), whereas major fault zones along plate boundaries are much weaker, for reasons that are not yet well understood.

We may usefully summarize the average stress state near faults by recalling the analysis from Section 4 of stress and energetics at a single point on an idealized fault surface with uniform properties. We showed that the initial, pre-slip shear stress τ_i is

$$\tau_i = \tau_a + \frac{1}{2} \Delta\sigma + \tau_r \quad (8)$$

where τ_a is apparent stress, σ is stress drop and τ_r is stress resisting fault slip. The heat flow constraint (Section 6) gives $\tau_r < 20$ MPa; seismic and geodetic estimates (Section 7) yield $\Delta\sigma = 0.1$ –10 MPa. These estimates argue that average values of τ_r and $(\tau_i - \tau_f)$ are small but [see Eq. (8)] leave open the possibility that initial stress τ_i could be large if τ_a were large. This might occur, if for example, the inertia of the accelerating fault blocks causes the resisting stress τ_r to overshoot the final stress τ_f , as sketched in Figure 2. However, such a process would lead to radiation of anomalous seismic energy (E_s) and be reflected in high values of apparent stress τ_a ($\tau_a = E_s/M_0$). Estimates of radiated energy from seismograms (Section 8) give $\tau_a = 1$ –10 MPa. These values then yield, using Eq. (8), an upper bound for initial stress τ_i of 20–40 MPa. This is consistent with an earlier upper bound estimate of 20 MPa obtained by Lachenbruch and Sass (1980) for the San Andreas fault.

This upper bound on initial stress averaged over the earthquake rupture plane has important implications for the strength of faults. At subduction thrusts this upper bound is much lower than the fault strength inferred from frictional slip experiments in the laboratory [Eq. (15c)]. It is marginally less than the same strength estimate for strike-slip faulting [Eq. (15b)]. At subduction zones, τ_i could only be as large as suggested by Eq. (15b) (~ 300 MPa average in the seismogenic upper crust) if τ_a were two orders of magnitude larger than observed. Therefore, the main weakening mechanism relative to the laboratory estimates, at least in the deeper parts of subduction zones, must be quasi-static. Constraints are poorer on the shallower parts of thrust faults and on strike-slip faults, leaving open the possibility that dynamic weakening could be more important there.

9.1 Weakening Mechanisms

The reasons for fault weakness has been debated for over 40 years, dating from the work of Hubbert and Rubey (1959) on the mechanics of slip on low-angle overthrust faults. Though many mechanisms have since been suggested, no single one has yet been universally accepted. Here we mention only some of the candidates we judge to be strong possibilities. Interested readers are referred to additional mechanisms mentioned briefly below and listed in the references section at the end of this chapter.

As shown by Eq. (9), very high fluid pore pressure in fault zones can, formally at least, overcome the effects of overburden pressure and permit slip at arbitrarily low shear stresses. This mechanism was originally suggested by Hubbert and Rubey (1959) to explain how large thrust sheets could be transported tens of kilometers when the weight of the overlying rock imposed frictional resisting stresses of several hundred megapascals or more on the fault. Through increasing elaboration over 40 years, the Hubbert–Rubey mechanism remains one of the leading candidates for reducing fault

strength. As applied to a strike-slip setting, Lachenbruch and Sass (1980) pointed out a possible limitation of the Hubbert–Rubey model, that near-lithostatic fluid pressure would produce pervasive hydrofracture normal to the least principal stress in the blocks adjacent to the fault. Rice (1992) pointed out that this difficulty could be overcome if very high fluid pressures were confined to the fault zone only, producing a fault that slips under very low shear stresses bounded by much stronger surrounding blocks where pore pressures were nearly hydrostatic. He suggested upward fluid flow into the fault zone from the ductile roots of faults, where pore pressure may be nearly lithostatic. However, Chery *et al.* (2000) have recently pointed out that unless the highly pressured fault zone is very narrow (~ 10 –100 m wide), such a model implies large, super-lithostatic vertical stresses in the fault zone, leading to plastic extrusion of fault zone rocks toward the Earth's surface. Furthermore, it seems questionable that very high pore pressures could be permanently confined within the fault zone when periodic large earthquakes create fracturing that extends from seismogenic depths to the surface.

A related class of weakening mechanism relies on transient pore pressure changes accompanying earthquake rupture. Sibson (1973) and Lachenbruch (1980) suggested fluid hydraulically confined within the fault zone during earthquake slip could be sufficiently frictionally heated to create high pore pressure via thermal expansion and a phase transition from water to steam. Sibson (1990) later proposed that fluid pressures in the bottom half of the seismic zone could transiently cycle between lithostatic and hydrostatic as a result of fracture permeability created during slip and resealing of these fractures by post-slip precipitation (“fault valve” behavior), and he cited field evidence from exhumed high angle reverse faults to support this model.

Dynamic weakening could result if frictional heat generation were sufficient to actually melt fault zone rocks during slip (McKenzie and Brune, 1972; Kanamori *et al.*, 1998; Kanamori and Heaton, 2000). This inference is supported by restricted occurrences of unusual fault zone rocks (“pseudotachylyte”) interpreted as products of melting during slip (Sibson, 1975). For temperature rises to be sufficient to produce melting, the zone of earthquake slip must be very narrow (a few centimeters or less), which may occur in some fault zones. However, the relative rarity of pseudotachylytes generally argues for lower resisting stresses and temperature rises during fault slip.

Another class of weakening models includes dynamic inertial effects. As mentioned in Section 8, theoretical models and analogue experiments show fault opening during dynamical slip, and if this occurs at seismogenic depths in the Earth it would be a weakening mechanism of major importance.

Additional weakening mechanisms include: (1) low intrinsic friction coefficient clays and related rocks (Wu, 1978; Wang *et al.*, 1979); however, note more recent laboratory experiments showing near-normal μ at upper crustal confining

pressure (Morrow *et al.*, 1992); (2) rotation of rounded fragments of fault gouge (Brune and Anooshehpour, 1997; Mora and Place, 1998); (3) dynamic compaction generating high pore fluid pressure (Sleep and Blanpied, 1992); (4) acoustic fluidization of fault gouge during slip (Melosh, 1996).

9.2 Inhomogeneous Fault Strength and Its Implications

Thus far we have discussed models of fault strength that are either explicitly homogeneous or rely largely on observations like heat flux and radiated energy that are integrated averages of stress effects. However, much of what is known and understood about faults indicates they are inhomogeneous in their physical properties and their effects over a wide range of scales. Surface maps show faults are often discontinuous and change in orientation along strike, and seismic and structural evidence often shows these variations persist at depth. Mappings of the distributions of both coseismic slip and moment release from large and great earthquakes show heterogeneity is the rule. Geodetic mappings of earthquake slip show slip magnitude varies by factors of 4–8 on the coseismic rupture (Fig. 9). Using Eq. (22) and a fault

zone width of 10 km, these observations indicate stress drop varying from 3 to 25 MPa along fault strike. Analysis of broadband seismograms from great earthquakes (e.g., Kikuchi and Fukao, 1987; Beck and Ruff, 1989) shows moment release rate is very nonuniform. Much of the energy radiated to teleseismic distances originates from restricted portions of the earthquake fault (see compilation of 21 such determinations in Thatcher, 1990, Fig. 4), indicating τ_a is also heterogeneous. Similar results have been reported from analysis of regional strong motion recordings of $M \sim 7$ earthquakes (Trifunac and Brune, 1971; Cohee and Beroza, 1994; Wald and Heaton, 1994). These observations thus indicate that if the average fault stress is low, the observed heterogeneity in $\Delta\sigma$ and τ_a require that the ambient stress distribution be strongly heterogeneous as well.

9.3 Conceptual Model

These observations suggest a simplistic fault zone strength model shown schematically in Figure 10. Its essential features include patches of strong fault located at the deepest parts of the brittle crust, where large earthquakes nucleate and where Eq. (15) suggests the highest shear stresses occur. These strong

FIGURE 10 Schematic of inhomogeneous strength model: (a) strong and weak regions are permanent; (b) strength varies from cycle to cycle or over long time intervals. Top, strike-parallel longitudinal section view of vertical strike-slip fault, with strong patches shaded. In (b), the strong regions from the previous cycle are shown outlined by dashed lines. Middle, steady-state surface heat flux plotted versus distance along fault strike. Bottom, map view of horizontal principal compressive stress axes along fault strike. In (b), orientations during the preceding cycle (Cycle 1) are shown “north” of fault, and from Cycle 2 to the “south.” B/D, brittle–ductile transition.

patches separate much weaker regions at shallower depths and along fault strike at depth.

The model shown in Figure 10 has some similarities with the “asperity” model of faulting inspired by ideas on the distribution of seismic and aseismic slip on plate boundary faults and by seismological mappings of moment release in large earthquakes (e.g., Wesson *et al.*, 1973; Kanamori, 1981; Lay *et al.*, 1982). In this view, the asperities are the locked patches of a fault which slip only during earthquakes, with much of the seismically radiated energy originating from these localized regions.

In the model of Figure 10, the strong patches could have a range of behaviors. They could slip locally with large dynamic stress drops during earthquakes, in which case large amounts of seismic energy will be radiated from these locations. Alternatively, stress drops here may be modest, in which case locally large amounts of energy will be dissipated by frictional heating. The strong patches could be permanent features of the fault zone or they could shift in location from cycle to cycle or over longer time intervals.

Earthquake stress release on high strength patches near the base of the seismogenic zone could be very important in dynamically driving slip at shallower depth. The dynamic model described by Brune (1999), suggested by analogue modeling in foam rubber (Brune, 1996), emphasizes the effect of large driving stresses available at depth due to the higher quasi-static strength there. In this model, near surface slip is driven by dynamic waves from the deeper portions of the fault, and large surface slip results even though ambient stresses there are very low. Similarly, in a lattice dynamics model of thrust faulting (Shi *et al.*, 1998), large displacements at shallow depths occur under very low prestress, again being driven by large dynamic stress drop at depth.

As discussed above, the reason why average fault zone strength is low remains uncertain. However, as suggested by Sibson (1990) and Rice (1992), fault zone stresses on the stronger patches could be moderated by the high ($\sim$ lithostatic) fluid pressures originating from below the brittle–ductile transition. Results from metamorphic petrology (Fyfe *et al.*, 1978) and study of geothermal systems (e.g., Fournier, 1999) show that ductile rocks are fluid saturated. Furthermore, fluid pressures are likely to be nearly lithostatic, because any cracks or fluid passageways to the brittle crust would be sealed by flow. However, earthquake rupture or steady-state aseismic slip could open contact between the hydrostatic and lithostatic regimes, decreasing resisting stress transiently during seismic slip, as in Sibson’s fault valve model or permanently, during steady-state creep. Dynamic weakening during earthquake slip could complement this process or independently supply the fault-averaged low strength required by our inhomogeneous model. This weakening mechanism would not, however, apply for aseismically slipping faults unless the aseismic behavior were a transient feature of the fault zone.

9.4 Role of Average Constraints on τ_r and τ_a

Although successful strength models must simultaneously satisfy the heat flux and radiated energy constraints, these constraints apply only for values of τ_r and τ_a averaged over the fault plane. In the case of heat flux, the constraint is also an average over time and applies over conductive timescales (approximately 100 ka or longer). Thus the requirement that $\tau_r < 10$ MPa on the San Andreas would still permit values consistent with Eq. (15b) over restricted portions of the upper crustal fault surface. If the most dissipative zone were not a permanent feature of the fault, the upper bound value of τ_r might more nearly represent the time-averaged strength of the entire fault zone. The heat flux constraint would appear to be much more stringent on the deeper portions of subduction thrusts, where Eq. (15c) would suggest resisting stresses of ~ 600 MPa under hydrostatic conditions at 30 km whereas observations permit no more than about 40 MPa at this depth.

The radiated energy constraint applies in the same averaged way as heat flux, and τ_a could locally be much higher than its mean value of 0.5 MPa. Indeed, τ_a values as high as 22 MPa are shown in Color Plate 13. In this regard it may be noteworthy that McGarr (1999) finds the upper bound values of τ_a obtained from seismology are approximately consistent with extrapolations based on laboratory rock mechanics and data from mining-induced seismicity (i.e., 15). This might be expected if some earthquakes ruptured only the high strength portions of an inhomogeneous fault.

9.5 Observation Implications

Observable effects of fault stress heterogeneity will differ depending on whether the strength distribution is permanent or varies from one earthquake cycle to the next or over longer timescales (Fig. 10). Permanent regions of high resisting stress (Fig. 10a) could produce significant frictional heating, but their effect on surface heat flux would be more subtle and difficult to detect than dissipation that is uniform along strike. This follows because laterally confined heat sources generate lower peak steady-state surface heat fluxes that decay more rapidly with distance than do 2D sources. In addition, for a fluid-saturated crust with enhanced fault zone permeability, along-strike advection of heat could spread out the effect of dissipative heating from a local source. If the strength distribution varied temporally (Fig. 10b), dissipative heating would migrate with time, and surface heat flux would become quasi-uniform on thermal conduction timescales.

If high and low strength regions were permanent fault features (Fig. 10a), temporal changes in principal stress orientations would be small or undetectable. If on the other hand, the zones changed from one earthquake cycle to the next (perhaps as slip minima from one earthquake were followed by high slip in a subsequent event), then stress orientations could change from cycle to cycle (Fig. 10b) and also change within

each cycle as the fault strengthened by accumulation of elastic stresses.

Mount and Suppe (1987) and Zoback *et al.* (1987) originally proposed that strength differences exist between the central creeping segment of the San Andreas fault (where compressive stresses are nearly normal to the fault), and the currently locked portion of the fault system further north (where these orientations are more oblique). In principle, determinations of principal stress orientations can also be used to map out stress heterogeneities on a more local scale. Hardebeck and Hauksson (1999) used a large suite of earthquake focal mechanisms to infer local variations in compressive stress orientations both along strike and perpendicular to the San Andreas system in southern California. Although it is tempting to attribute these results as evidence for fault strength heterogeneity, facile interpretations are frustrated by the considerable complexity of the derived orientations, which show rapid spatial changes and seldom decay to stable values far from the San Andreas. While perhaps containing evidence for fault stress heterogeneity, we suspect some of the variability is also due to effects other than simply the ambient stresses on the faults themselves. These include: (1) unavoidable limitations of the inversion method (e.g., inadvertently including more than one stress regime in a single stress field determination); (2) biasing of inversions by using focal mechanisms from faults subparallel to the San Andreas; (3) local stress perturbations (Turcotte, 1982) due to significant crustal thickness and lithospheric density variations across southern California; and (4) lateral rheology variations that modify fault-generated stresses (Chery *et al.*, 2000).

9.6 Observational Tests

We do not see simple tests of either the conceptual model of fault zone stress shown in Figure 10 or those previously proposed by others. Like previous reviewers (e.g., Hickman, 1991), we support direct observation of the constitutive properties and physical state of active faults through drilling and sampling. Plans are proceeding to carry out such an experiment to a depth of ~ 4 km on the San Andreas fault near Parkfield, California (Hickman *et al.*, 1994) and drilling is now expected to begin during 2003.

Because seismically radiated energy is such a diagnostic measure of stress changes during faulting, more precise estimates, particularly those obtained in the near field of large and great earthquakes, would be especially valuable. In particular, such measurements would be one means of testing our suggestion that apparent stresses obtained from radiated energy estimates are low because τ_a is averaged over a rupture surface where quasi-static or dynamic strength is heterogeneous. More generally, high quality near-field recordings of strong ground motion like those now becoming available for the 1999 $M_w = 7.6$ Chi-Chi (Taiwan) earthquake will constrain the

dynamics of fault slip through mappings of the stress-slip history over the entire rupture plane.

Acknowledgments

Stimulating discussion was provided by A.G. McGarr and S.H. Hickman, both of whom provided insightful reviews of the manuscript. Thorough reviews were also provided by Y. Fialko, A.H. Lachenbruch, and R.H. Sibson. Apparent stress estimates for teleseismic data, many of which are unpublished, were kindly supplied by G.L. Choy.

Implications of Crustal Strain During Conventional, Slow, and Silent Earthquakes

M.J.S. Johnston

US Geological Survey, Menlo Park, USA

A.T. Linde

Carnegie Institution of Washington, Washington, USA

1. Introduction

Uniform block-slip motion consistent with simple shear on locked fault segments is the primary feature apparent in geodetic measurements of strain accumulation along plate boundaries (Savage, 1983). However, almost every aspect of fault failure is nonlinear in character. This premise derives from theoretical models (Kostrov, 1966; Richards, 1976; Andrews, 1976; Freund, 1979; Rice and Rudnicki, 1979; Rice, 1983, 1992; Stuart, 1979, Stuart and Mavko, 1979; Das and Scholz, 1981; Rundle *et al.*, 1984; Tse and Rice, 1986; Lorenzetti and Tullis, 1989; Segall and Rice, 1995; Shaw, 1997; Miller *et al.*, 1999) and laboratory-generated frictional failure of crustal materials (Dieterich, 1979, 1981; Mogi, 1981; Mogi *et al.*, 1982) which predict accelerating deformation will occur before dynamic slip instabilities, better known as earthquakes.

To investigate this physics of fault failure, it has increasingly become obvious that new techniques, with capability to resolve strain at better than 1 part per billion (ppb), are needed. Geodetic and GPS strain measurements with resolutions with approximately 0.4 parts per million (ppm) resolution on 5-km baselines may help with some broadscale problems such as fault interaction, viscoelastic response (Thatcher, 1983; Pollitz *et al.*, 1998), coseismic and postseismic response of large earthquakes (Langbein *et al.*, 1983; Bock *et al.*, 1997; Burgmann *et al.*, 1997), but issues regarding the type of slip transients, the relative frequency of slip transients, fault creep, earthquake nucleation, pore pressure changes, slow earthquakes and silent earthquakes (where moment release is usually below that typically released for a $M = 5$ earthquake), are unlikely to be resolved with these techniques. Some strain transients, such as those occurring postseismically have been known for a long

time (e.g., Langbein *et al.*, 1983; Thatcher, 1983). Many others, including those occurring aseismically, are not well documented or understood even though they may play important roles in the fault-failure process.

From previous strain studies (Johnston *et al.*, 1987; Wyatt, 1988), and discussed further here, it is now generally clear that entire rupture zones do not exhibit nonlinear behavior as implied by “preparation zone” terminology (Sadovsky *et al.*, 1972) and some theoretical models of the rupture process (Mjachkin *et al.*, 1975; Tse and Rice, 1986). Nonlinear (accelerating) deformation is not apparent in arrays of sensitive strain and tilt instruments installed throughout regions that have subsequently ruptured. Instead, rupture over a large fault length appears to be triggered by failure of smaller regions with higher strength, and this rupture draws on the elastic strain energy in the region. The expected signals should have occurred during the period immediately preceding rupture initiation. Also, the total slip moment (preseismic, coseismic, and postseismic) could be determined when each phase of the rupture process is identified.

If failure initiates in small regions of high strength and expands to any arbitrary size until stopped by another mechanical or geometrically strong barrier, this failure still has an easily identifiable form (nonlinear exponential-like strain increase). Unfortunately, detection of any preseismic slip and, more importantly, prediction of the final rupture size, will be difficult to achieve (Brune, 1979) because the total moment release during this time is only a small fraction of that released coseismically.

The timescale of failure is also not clear although the absence of obvious tidal triggering (Heaton, 1982) implies the final stage of failure occurs at periods comparable to, or

shorter than, the major earth tidal periods (12.42, 23.93, 25.82 h, etc.). Numerous observations (Rikitake, 1976; Mogi, 1985) indicate cases when this appears to be true. The shortest timescale for nonlinear strain can be estimated from subcritical crack growth in brittle materials (Atkinson, 1979). However, it is expected that the presence of fluids should stabilize and slow down the process of cascading crack fusion in rock at the temperatures and pressures expected in the upper 10 km of the Earth's crust (Rice and Rudnicki, 1979), as shown in Figure 1. Strain during the final stages before failure accelerates dramatically in comparison with earlier periods, with maximum strain occurring, as expected, at the point of rupture.

Laboratory experiments also indicate that these last stages of failure of crustal rock (sometimes termed tertiary creep) are the end result of a process of cascading crack coalescence which results in strain time histories similar to those shown in Figure 1 (see, for example Mogi, 1985). Large-scale laboratory models with preexisting artificial faults, either with or without gouge material, exhibit similar behavior (Dieterich, 1979; Mogi, 1981, 1985; Mogi *et al.*, 1982).

If the timescale of failure initiation is between one second and one day, continuous measurements of the state of strain and tilt in the Earth's crust near moderate to large earthquakes should quickly provide detailed information on time history, failure mechanics, and size (moment) of the prerupture failure. This assumes, of course, that these measurements are recorded at a sensitivity sufficient to detect failure nucleation in the last few hours to seconds before rupture occurs.

Observations of crustal strain at high sensitivity near large earthquakes during the final stages before rupture are unfortunately rare, and knowledge of the timescale and mechanics of failure is therefore limited. This has resulted largely from the infrequency of earthquakes and the poor areal coverage with adequate instrumentation. With the installation of

borehole strain and tilt arrays along the San Andreas fault system and in other seismically active places during the last ten years, data are now accumulating. Along the San Andreas fault, many events have occurred for which we have near-field recordings at high sensitivity although only two for which the magnitude was greater than 7. In addition, we can call upon events recorded with similar instruments in Japan (e.g., Sacks *et al.*, 1978, 1979) and Iceland (Linde *et al.*, 1993).

In this paper we use these data to: (1) document the implications of crustal strain observed during fault creep events; (2) compare the expected form of slip waves on active faults with observations of crustal strain recorded near these faults; (3) compare the coseismic strain generated by earthquakes with calculations from simple elastic dislocation models of the events derived from seismic observations to determine the ratio of total moment release to seismic moment release; (4) discuss some observations of "slow" and "silent" earthquakes, and finally, look at the state of strain during the last few hours to the last few seconds before earthquakes and the implications this has for the issue of earthquake nucleation, earthquake prediction, and current theory. In particular, we use these strain observations to estimate the maximum pre-seismic slip moment release as a fraction of the observed seismic moment release and to place upper limits on nucleation source size.

2. Experimental Design and Measurement Precision

2.1 Basic Measurement Limitations

Strain measurements have historically been made along active faults using long baseline geodetic techniques. Sampling was approximately annual and the sensitivity was about 1 ppm. Unfortunately, these techniques lack the sensitivity required to detect short wavelength (5 km) slip waves propagating along faults, coseismic strains for earthquakes with $M \leq 5$, details of aseismic slip, slow earthquakes, and silent earthquakes. New arrays of GPS instrumentation will improve observations of secular motions because of their increased spatial coverage but the sensitivity in the critical band from months to milliseconds is still several orders of magnitude worse than that attainable with borehole strainmeters. Figure 2 shows the comparative resolution of the different measurement techniques as a function of period. Near-surface strainmeters always had more short-term sensitivity than geodetic observations but did not have the long-term stability or spatial averaging to determine long-term strain rates. Records were also compromised at times by effects of rainfall (Wolfe *et al.*, 1981; Yamauchi, 1987). Lower-noise strain data were sometimes obtained by placing strainmeters in deep tunnels and mines. However, a real breakthrough resulted when strainmeters were installed in deep boreholes far from surface noise sources.

FIGURE 1 Normalized strain time history arising from fault instability models with and without the presence of water (from Rice and Rudnicki, 1979). Θ_{prec} refers to the precursor time defined by Rice and Rudnicki (1979). B' is the onset of instability, D' is the onset of dynamic instability and the dashed portions of the curves indicate where the numerical calculations were truncated.

FIGURE 2 Comparative resolutions of crustal strain rates for borehole strainmeters, differential GPS, EDM and tilt sensors as a function of period (after Langbein and Johnson, 1996). (Note: GPS and EDM strain assume an 8 km baseline.)

Figure 3a shows strain noise spectra for different depths of burial. At a depth of burial of 200 m noise spectra from strainmeters in a variety of geophysical environments are identical within the errors. Figure 3b shows that the same spectra are obtained whether the strainmeter is in a volcanic region (POPS), within a few hundred meters of a currently quiescent but active region of the San Andreas fault (PUBS), or near a creeping fault (GH2S). Similar spectra are obtained at other sites either near to, or many tens of kilometers from the San Andreas fault.

2.2 Experimental Techniques

The location of the various borehole strainmeters along the San Andreas fault in California is shown in Figure 4. The borehole strainmeters shown as black dots measure dilatational strain (Sacks *et al.*, 1971), whereas those shown as black squares measure 3-component or tensor strain (Gladwin, 1984; Gladwin *et al.*, 1987). The sensitivities of the dilatometer and tensor strainmeters are less than 10^{-11} and less than 10^{-9} , respectively. Each of the strain sensors is installed at depths between 100 and 200 m and each detects strains at levels at least 20 dB below those obtained on near-surface strainmeters (Johnston and Borchardt, 1984). The dynamic range exceeds 140 dB (Sacks *et al.*, 1971; Sacks, 1979; Gladwin, 1984) over the period band of 0.1 sec to several months. During installation, the strain sensors are cemented in the borehole with expansive grout. The borehole is then filled to the surface with cement to avoid long-term strains from hole-relaxation effects and re-equilibration of the aquifer system.

These broadband instruments record data over ten decades of frequency. Strain from atmospheric pressure loading of the

FIGURE 3 (a) Strain noise power as a function of depth beneath the Earth's surface. (b) Comparative strain noise power over ten decades of frequency for different sites in California. PUBA is within 500 m of the San Andreas fault in southern California, GH1S is within 1 km of a creeping segment of the San Andreas fault near Parkfield, and POPA is near an active volcanic caldera in eastern California.

Earth's surface and from the solid earth tides (including effects from ocean loading) are the most obvious signals continuously evident in the data. Superimposed on these are straingrams from local and teleseismic earthquakes. Atmospheric pressure, earth tide and ocean loading effects can be readily predicted and removed from the data (Rabbel and Zschau, 1985; Tamura *et al.*, 1991; Agnew, 1997). Although other corrections, such as for the distortion of strain fields due to nearby extreme topography are sometimes necessary (Harrison, 1976), strain

FIGURE 4 Borehole crustal strain sites in California and moderate earthquakes with magnitudes greater than 5 (shown as stars) that were recorded at these sites.

can generally be modeled with dislocations in elastic or viscoelastic half-space (Matsu'ura and Tanimoto, 1980; Okada, 1985, 1992; McTigue and Segall, 1988).

Data from these strain instruments are transmitted in 16-bit digital form through the GOES weather satellite to Menlo Park, California for processing (Silverman *et al.*, 1989). The strain sensors together with the sites are calibrated using ocean-load corrected earth tides (Linde and Johnston, 1989; Linde *et al.*, 1992; Hart *et al.*, 1996). This calibration is generally repeatable to within 1%.

3. Strain Fields and Geophysical Implications

3.1 Fault Creep Events

Surface observations of episodic displacement of active faults are usually termed fault-creep events. These creep events on the San Andreas might be argued to be a special form of slow earthquakes. However, previous work (Johnston *et al.*, 1976, 1977; McHugh and Johnston, 1977, 1978, 1979; Goulety and Gilman, 1978; Evans *et al.*, 1981; Gladwin *et al.*, 1994) indicates that the event-like nature of fault-creep events results primarily from complex failure of the near-surface fault zone materials at depths typically shallower than several hundred meters rather than fault failure at seismogenic depths.

Earthquake shaking of the near-surface soils can also trigger creep events (Simpson *et al.*, 1988).

A network of strainmeters [dilatational strainmeter (DS) and tensor strainmeter (TS)] installed at Parkfield (Fig. 5a) provides examples of the primary features of crustal strain during fault creep. One such example is the event on 6 October 1997, recorded on XVA1 and XPK1. The rupture length is limited since this event was not recorded at XTA1 just south of XPK1 nor at XMD1 to the northwest of XVA1. Its minimum dimension could be as small as 3 km (the distance between XVA1 and XPK1). If we search the strain records from the strainmeters, FRDS, DLDS, VCDS and EDTS, surrounding this section of the fault, we find a detectable strain transient above the noise only on the closest strainmeter FRDS (Fig. 5b). This signal indicates a compressive signal of about 15 nanostrain. A small negative change of about a nanostrain may have occurred on DLDS. An upper estimate of the depth of this creep event can be determined if we model the event using Okada's (1985, 1992) dislocation formulation using a length of 4 km, a displacement of 2.5 mm (observed at XVA1), and determining the likely depth that would generate a strain transient of 15 nanostrain at FRDS and less than a few nanostrain at the other sites. The lower plot on Figure 5b shows calculated strain amplitude as a function of the width of the creep event. It is apparent that the width cannot exceed a few hundred meters. Similar depths are obtained for numerous other creep events. These data support the notion

FIGURE 5 (a) Location of the dilatational strainmeters (FR, DL, JC, VC, GH1 and GH2), tensor strainmeters (FLT, DLT and EA), and creepmeters (XMM1, XMD1, XVA1, XTA1, CRR1, XPK1, XGH1, and WKR1) at Parkfield, California. The fault patch shows the location of the creep event discussed in Figure 5b. (b) Strain and creep time histories during the creep events recorded at XVA1 and XPK1 on 6–7 Oct. 1997. Creep records are shown in the top of the upper plot, strain records from FR and DL are shown in the bottom of the upper plot. The lower plot shows the calculated strain as a function of fault slip width at the two strain sites FR and DL.

that creep events result from shallow slip waves in the upper few hundred meters of the fault.

Similar conclusions were evident in data from arrays of creepmeters, strainmeters, and tiltmeters separated by only a few hundred meters in other parts of the creeping section of the San Andreas fault (McHugh and Johnston, 1979; Evans *et al.*, 1981; Goulety and Gilman, 1978). These data also indicated complexity in propagating inhomogeneous slip waves on scales of a few hundred meters. Furthermore, indications of deep slip episodes in near-fault strain data (Johnston *et al.*, 1977; Langbein, 1981; Linde *et al.*, 1996) have not been found to correspond to the times of surface creep events although the long-term fault displacement rates are mostly reflected in long-term creep rate data (Schulz *et al.*, 1982). This view of the event-like character of surface creep events is consistent with the suggestions (Marone *et al.*, 1991) that near-surface fault materials exhibit velocity strengthening but cannot ultimately sustain the rapid slip associated with earthquake source motions. In contrast, materials at seismogenic depths primarily exhibit velocity weakening as expected from theoretical work on rate and state variable friction (Ruina, 1983; Dieterich, 1994). Episodic near-surface creep events are thus not considered to be slow earthquakes.

3.2 Fault Slip Waves

The suggestion that regional strain waves may propagate along active faults has been around since the 1970s (Kasahara, 1979; Savage, 1971; Ito, 1982; Kasahara *et al.*, 1983) although little support has yet been found. Slip waves over the fault face with amplitudes of a few millimeters generate coherent strains exceeding 10^{-7} within a few kilometers of the fault. Signals of opposite form occur on opposite sides of the fault. Figure 6b shows the predicted signals on several instruments at Parkfield for a slip wave with an amplitude of 10 mm between 5 km and 10 km that propagates past several strainmeters installed within a few kilometers of the San Andreas fault, shown in Figure 6a. If these slip waves occurred with propagation velocities from kilometers per month to kilometer per minute they would be readily observable on the strainmeter arrays. Thus far they have not been seen. These slip waves could occur but not be detected on the current strainmeter arrays if the velocities are more than ten times slower (i.e., kilometers per year). Neither would these slip waves be detected in the semicontinuous two-color EDM or continuous GPS measurements in the Parkfield area unless the amplitudes were 10–100 times larger.

Nevertheless, this idea has recently resurfaced in 1995 (Press and Allen, 1995) and, again in 1998, with the suggestion (Pollitz *et al.*, 1998) that slip waves should also occur from time-dependent viscoelastic response from distant subduction earthquakes. The expected amplitudes are 10^{-8} with a timescale of several years.

FIGURE 6 (a) Map of the Parkfield region illustrating a hypothetical slip wave propagating between 5 km and 10 km beneath the surface array of strain and creep monitoring sites. (b) Predicted strain time histories for a 5 km wide slip wave propagating between 5 km and 10 km depth past several borehole strainmeters in Parkfield. The slip amplitude is 10 mm. For clarity only four strain-time records are shown.

4. Earthquakes

The coseismic observations can be separated into two parts, the dynamic straingram and the static strain field offset generated by the earthquake. Theory of the strain seismogram can be found in Benioff (1935) and Richards (1976) and will not be pursued further here. The observation of strain offsets from

TABLE 1 List of earthquakes and Observed and Calculated Coseismic Strain Offsets. Details for some earthquakes were Obtained from Eaton (1985 and unpublished), Johnston *et al.* (1986), L. Jones (personal communication), Lester (personal communication), Shimazaki and Somerville (1978), and others from the Northern California Data Center. The code name following the observed strain offsets in column 4 refers to the instrument on which the offset was observed. The locations of these instruments are shown in Figure 4

earthquakes has a long history. Early hopes that these offsets could be observed teleseismically (Press, 1965) have not been realized. The primary reason seems to be that tilt and strain observations recorded under conditions of high acceleration in the cracked and fractured near-surface material in tunnels, caves and shallow boreholes, are not reliable because the materials and coupling are not stable (McHugh and Johnston,

1977). Installation of instruments in expansive cement in deep boreholes appears to have solved this problem (Sacks *et al.*, 1971, 1979; McGarr *et al.*, 1982). Data now show that coseismic strain steps can be recorded reliably.

Many examples have been recorded with the network of deep borehole instruments along the San Andreas fault. The best examples are listed in Table 1. For all the events shown here, clear strain offsets have been recorded. An example of the observed strain recorded on the nearest borehole strainmeter (PU) for the $M_w = 6.0$, 1 Oct. 1987, Whittier earthquake is shown in Figure 7a. This, and other similar offsets can be compared with the strain expected at each strainmeter location using the simplest model of each corresponding earthquake. These elastic dislocation models (Press, 1965;

Okada, 1985, 1992) assume the moment of the earthquake is generated by uniform slip over a rupture plane that is indicated by the aftershock zone. An example of such a simple dislocation model for the 1987 Whittier earthquake is shown in Figure 7b. In this case the seismically determined moment is 1.4×10^{18} N m, the aftershock zone measures 8 km by 13 km at a depth of 15 km, with a dip of 40° down to the northeast and a strike of N62W. For these dimensions and assuming a shear modulus of 3×10^4 MPa, the slip expected for the earthquake is about 57 cm.

Similar models are routinely generated for the many tens of earthquakes with $M \geq 5.0$ for which we have strain offsets recorded. The calculated and observed offsets for the largest are listed in Table 1 and are plotted in Figure 8. The observed and calculated offsets are in good general agreement except for one example (marked with ?) recorded on the instrument EVSS. Because this instrument was installed just above a large fracture zone, nonlinear effects caused by the accelerations from the seismic waves are more likely to be significant. Thus the total moment release for these earthquakes on the San Andreas fault appears on average to be about 20% larger than that released seismically. Important implications of this general correspondence between observed and calculated strain steps are: (1) that observed strain steps recorded immediately after large earthquakes can be used to make a rapid, albeit preliminary, estimate of the moment of these earthquakes, and (2) crustal response at periods of minutes to hours is still largely elastic.

Postseismic responses observed in these data do not occur unless the earthquake magnitude is greater than $M = 7$, although some effects are sometimes apparent for earthquakes in the $M = 6-7$ range. Most of these effects are due to afterslip,

FIGURE 7 (a) Observed strain on 1 Oct. 1987 at PU showing the strain offset generated by the $M_w = 6$ Whittier Narrows earthquake. The variation in the upper plot is due to earth tides. These are predicted and removed in the lower plot. (b) Model of the Whittier Narrows earthquake showing comparison between the observed and predicted strain offsets.

FIGURE 8 Observed coseismic strain offsets as a function of calculated offsets from simple dislocation models of the earthquakes listed in Table 1. See text for comments on point labeled ?.

but other contributions may result from triggered slip on other faults, as suggested by Sacks *et al.* (1979, 1982), to explain postseismic changes following the 1978 Izu, Japan, earthquake. Other short-term and longer-term effects may result from aquifer system response to the incoming seismic waves as observed by Wyatt *et al.* (1994) following the 1992 $M_w = 7.3$ Landers earthquake. In this case the time constant will be determined by the diffusion time constant. Transient strains and tilts related to fluid-diffusion effects triggered by the passage of seismic waves are very evident in measurements taken near the water table (McHugh and Johnston, 1977). The clearest postseismic strain signals have been observed for the larger earthquakes [e.g., Parkfield, 1966 (Smith and Wyss, 1968), Landers, 1992 (Johnston *et al.*, 1994), Loma Prieta, 1989 (Johnston *et al.*, 1990), and Imperial Valley, 1979 (Langbein, *et al.*, 1983)]. These data suggest power law slip in the upper few kilometers with some short-term aquifer re-adjustment effects.

4.1 Slow and Silent Earthquakes

Slow earthquakes refer to fault slip episodes at seismogenic depths that occur with some accompanying seismic radiation in the normal seismic frequency bands. Although long expected to occur (see for example, Kasahara, 1980), little direct evidence for their existence has been found in the few broadband deformation data sets obtained along active faults with enough sensitivity to detect these events. Several different types of slow earthquakes are expected. Slow earthquakes, that precede, and evolve, into “normal” earthquakes have been inferred for the great 1960 Chilean earthquake (Kanamori and Cipar, 1974; Cifuentes and Silver, 1989; Linde and Silver, 1989) and the 1992 $M_w = 7.6$ Nicaragua earthquake (Kanamori and Kikuchi, 1993). Slow earthquakes that follow “normal” earthquakes have been reported following the 1978 $M = 7$ Izu-Oshima earthquake (Sacks *et al.*, 1982), and silent earthquakes with no immediate associated seismicity have been suggested as the cause of strain transients recorded several days before the $M = 7.3$ Japan Sea earthquake (Linde *et al.*, 1988) and with the 1992 event at Sanriku-Oki, Japan (Kawasaki *et al.*, 1995). Large slow earthquakes with related but minor aftershock-like seismicity have occurred on three separate occasions on the San Andreas fault (Linde *et al.*, 1992; Johnston, 1997; Johnston *et al.*, 1998).

Indirect evidence for slow earthquakes has also been proposed on the basis of enhanced tsunami generation (Satake and Kanamori, 1977), anomalous normal modes (Kanamori and Anderson, 1975; Beroza and Jordan, 1990), and anomalous P arrivals (Kanamori and Kikuchi, 1993). Overall, when compared to the occurrence rate and moment release of conventional earthquakes, it would be fair to say from the limited near-fault strain data that slow earthquakes are a relatively rare phenomenon on active faults and contribute only in a minor way to total moment release. Nevertheless, they may play an

important fundamental role in stress transfer and earthquake triggering (Simpson and Reasenber, 1994; Harris, 1998).

The most important multiple slow earthquake on the San Andreas fault occurred with about a five-day duration in early December 1992, to the north of San Juan Bautista, California (Linde *et al.*, 1996). Other events were observed in 1996 and 1998. The 1992 sequence was recorded on three near-fault borehole strainmeters and two surface creepmeters along a 10 km section of the fault. The event was accompanied by minor seismicity that was obviously related to the strain data and culminated in surface rupture recorded on a surface creepmeter at the southern end of the strain array. Aseismic moment release for this event totaled about $5\text{--}6 \times 10^{16}$ Nm, equivalent to about a $M = 5.1$ earthquake, whereas seismic moment release was more than 100 times less.

Borehole strainmeters at the sites shown in Figure 9a detected large slow coherent strain changes from 10 Dec. to 15 Dec. 1992. The overall event stands out clearly in the

FIGURE 9 (a) Location of borehole dilatational strainmeters EVS, SRL, borehole three-component strainmeters SJS, and creepmeters XSJ2 and XNY with respect to the seismicity (squares) on 11–14 Dec. 1992, associated with a slow earthquake near the town of San Juan Bautista, California (see text). (b) Fault cross-section from A to A' in (a) showing the locations of earthquakes following the slow earthquake in Dec. 1992, in relation to the position of the strain and creep instruments along the fault.

long-term data as the largest event of this type we have seen on these instruments. A swarm of minor earthquakes (after-shocks?) occurred in this region at the same time. These earthquakes were relocated with a 3D velocity model and their locations are shown on Figure 9a with a symbol size that relates to magnitude and in cross section in Figure 9b. The cross section (indicated by AA' in Fig. 9b) shows the location of the earthquakes as a function of depth and position relative to the surface instruments. The seismicity outlines a crescent or "donut" shape on the section of fault beneath and between the strainmeters SRL and SJS from a few kilometers to about 8 km deep.

Figure 10a shows the data recorded on the three strainmeters as a function of time. The event began relatively rapidly on 11 Dec. 1992 followed by a slow exponential decay over the next eight days. The long-term decay was interrupted by a series of slow events, labeled A to E, from 11 Dec. to 15 Dec. Some indication of surface creep is evident on XNY following events A, C and E but no surface displacement is evident at XSJ2 until 14 Dec.

A $M=3.1$ earthquake occurred about two hours before the start of event A and two earthquakes of $M=3.3$ and 3.2 occurred within the first and third sample interval on both instruments (earthquakes 1, 2, and 3 in the center of Fig. 10a). Two $M=3.7$ earthquakes (earthquakes 5 and 6) occurred on the next day during event C on both instruments. Smaller earthquakes preceded and followed this event. Coseismic strain changes for all earthquakes are negligible. Because of the instrument sampling intervals, we cannot say with certainty whether these earthquakes preceded or followed the strain events but obviously they are causally related.

Although there are too few observation points to make a robust determination of the source model through formal inversion techniques (Bevington, 1969), we use forward quasi-static modeling to estimate the physical parameters of the simplest physical model that is consistent with the data. Source models are restricted to right-lateral slip segments on the San Andreas fault located in the region of microseismicity and observed surface creep. We search for the simplest quasi-static models that provide consistency with strain amplitudes and duration and surface creep since the strain changes are slow. The best model is shown in Figure 10b and comparison between model predictions (fine lines) and observations (thick lines) are shown on Figure 10a. The model details are generally similar to those given in Linde *et al.* (1996) but it includes three episodes of 3 mm of deeper slip in the region of seismicity, shown in Figure 9b, and slightly different values, shown in Figure 10a, to those used by Linde *et al.* (1996) in the upper section to get a better fit. The event E, coincident with surface creep on XSJ2, is due to surface slip on a patch indicated by W in Figure 10b that has previously failed repeatedly (Gladwin *et al.*, 1994). On this patch, slip of 5 mm with rupture velocity of 0.2 m sec^{-1} provides good agreement with data on SJS.

FIGURE 10 (a) Detrended strain data from dilatometers SRL and EVS and tensor strainmeter SJS for the period 10–20 Dec. 1992. Effects from earth tides and atmospheric pressure loading have been predicted and removed from the strain records. The tensor strain data have been converted into fault parallel shear γ_1 , NS or EW shear γ_2 and areal strain. Shown also are fault creep data from creepmeter XSJ2 and earthquakes (numbered 1 through 7). Included are comparisons between observed (thin) and calculated (thick) strain-time histories resulting from the simplest model (see text) used to fit the overall strain record and all the slip episodes – subevents A, B, C, D and E discussed in the text. (b) Quasi-static model used to calculate the amplitudes and timescales of the sequence of slow earthquakes beneath San Juan Bautista in Dec. 1992. (See text for description of details.)

Event C has different strain character on SRL than on SJS consistent with changes in the near-surface strain field as the source geometry changes. We have examined all possible model areas between the two instruments and find

the only viable solution results from 2.5 cm of slip on a patch Z. The rupture propagates slowly upward with an exponentially decreasing rupture velocity of 0.35 m sec^{-1} resulting in the sign reversal at SRL and the unidirectional changes at SJS.

For the remaining events, strain amplitude ratios cannot be satisfied by uniform slip over a single source area. We require a combination of slip on segments X, Y, and XY shown in Figure 10b. We limit the top of Y to be 0.3 km from the surface for consistency with the lack of creep until 14 Dec. The top of X is 0.1 km deep. We have reasonable control of the extent though the ends could be varied by about 1 km without significantly degrading the fit to the data. Uniform slip that decays with time on X, Y, and XY satisfies the data. This model has slip on X, Y, and XY of 3.7 mm, 3.6 mm, and 3 mm for A, 7.0 mm, 2.9 mm, and 3 mm for B, and 9.2 mm, 8.5 mm, and 3 mm for D (as shown on Fig. 10b) with time constants of 40 min for A, 15 h for B and 43 h for D.

The sequence of events starts with initial slow slip over all XY (event A), followed by slower slip over all XY (event B). Triggered slow upward rupture propagation over Z generates event C, and is followed by continued slow slip over XY (event D) and surface failure recorded on the creepmeter XSJ2 (event E).

The total moment release is $4.5 \times 10^{16} \text{ Nm}$. This is approximately equivalent to a $M=5$ earthquake. In contrast, the seismic moment release was $7 \times 10^{14} \text{ Nm}$ (a factor of 76 smaller than the total slow earthquake moment).

The microseismicity that was associated with this sequence occurred in a manner that was clearly related to the near-fault strain. Fitting of a simple exponential relaxation function of the form

$$f(t) = C(1 - \exp^{-at}) \quad (1)$$

to both the strain data and the cumulative earthquake number indicate similar time constants, $(1/a)$, of about 2.5 days. The occurrence of these slow events, and later events in 1996 and 1998 (Johnston, 1999), has reduced strain energy and has thus reduced (at least temporarily) the likelihood of a large damaging earthquake in this area, in contrast to suggestions by Behr *et al.* (1990).

4.2 Strain Redistribution

Strain redistribution has been clearly observed following each of the largest earthquakes in the San Andreas fault system. The best examples have been obtained for the 1992 Landers earthquake (Wyatt *et al.*, 1994; Johnston *et al.*, 1994), the 1989 Loma Prieta earthquake (Johnston *et al.*, 1990), and the 1987 Whittier earthquake (Linde and Johnston, 1989). Further details of strain redistribution following the Loma Prieta earthquake can be found in Burgmann *et al.* (1997) and Mueller and Johnston (2000).

5. Earthquake Nucleation

As pointed out earlier, laboratory observations and modeling efforts suggest that fault failure occurs when displacements exceed those for peak shear stress. Increased deformational “weakening” occurs before the dynamic slip instability that results in an earthquake. In rock mechanics terminology this is called “tertiary creep” (Jaeger and Cook, 1976). In terms of laboratory-determined rate or state-dependent friction (Ruina, 1983; Dieterich, 1994), it is called “slip weakening.” That nonlinear strain precedes rupture has provided hope that detection of these strain changes will lead to a method for earthquake prediction. At issue is the scale on which this occurs. Since continuous strain measurements near moderate to large earthquakes thus far have failed to detect any indications of exponentially increasing strain (Johnston *et al.*, 1990, 1994; Wyatt, 1994; Abercrombie *et al.*, 1995), the scale must be small compared to the eventual rupture size. Here we discuss just how small this might be.

5.1 Field Observations

We choose just one typical example of short-term and intermediate-term strain obtained before, and immediately above, a moderate magnitude earthquake to illustrate this scale. The event we choose was one of three $M=5$ earthquakes that occurred beneath the Parkfield strainmeter array shown in Figure 11a. A cross section of these events is shown in Figure 11b. The first was a $M=4.7$ earthquake that occurred on 31 Oct. 1992. The second was a $M=4.8$ earthquake that occurred on 20 Nov. 93 and the third was a $M=5$ earthquake on 24 Dec. 1994.

Figure 12a shows the strain data from FRS and DLS for the $M=5$ event on 20 Dec. 94 for the five days before and after this earthquake. The vertical scale is in 10 nanostrain units in the upper plot that shows the strain offsets (+31 nanostrain at FR and −94 nanostrain at DL) generated by the earthquake. The scale is expanded in the lower plot by a factor of 50 (0.5 nanostrain units).

Figure 12b (upper) shows the strain seismograms for this earthquake recorded on these two instruments. The expanded timescale in the lower plot shows the data for these events in the last seconds before rupture. Here the vertical scale is 1000 nanostrain. Figure 12c shows the strain vertical scale expanded by 100 in the upper plot (units of 10 nanostrain) and by 10 000 in the lower plot (units of 100 piconstrain). The occurrence time of the earthquake is shown with an arrow. Strain changes, if they occurred before the event, appear to be less than 0.01 nanostrain. Similar observations were obtained for the other two $M=5$ earthquakes.

It is apparent for these events, and for the 17 or so moderate to large earthquakes for which we have near-field strain data, that none of the strain records shows any indication of accelerating strain prior to rupture at our ability to resolve

FIGURE 11 (a) Map of Parkfield showing the location of three near-magnitude 5 earthquakes beneath the dilatational strainmeters VC, FR, and DL on 20 Oct. 1992, 14 Nov. 1993, and 20 Dec. 1994. The locations of the various events are shown in cross section in (b). (b) Seismicity cross section showing the location of three near-magnitude 5 earthquakes beneath the dilatational strainmeters VC, FR, and DL on 20 Oct. 1992, 14 Nov. 1993, and 20 Dec. 1994. Also shown is the hypocenter of the 1966 Parkfield mainshock (Star).

strain (0.01 nanostrain over seconds and 1.0 nanostrain over days). This does not mean that accelerating strain is not occurring, only that it is below our measurement resolution. Another way of saying this is that the maximum possible preseismic slip moment in the eventual hypocenter produces strains at the instrument that are less than, or equal to our measurement resolution.

The maximum possible precursive slip moment expressed as a percentage of coseismic moment is plotted against seismic moment for these earthquakes in Figure 13. In general, moment release before these earthquakes is less than a few percent and perhaps less than 0.1% if we take the later data for which the signal-to-noise is best (Johnston *et al.*, 1990, 1994; Wyatt, 1994). What this most likely means is that rocks do indeed fail as expected but that the initial slip is small and localized compared to the final or total slip. The ratio of total slip to nucleation slip is thus large and rupture initiation is inhomogeneous in agreement with a variety of theoretical and seismological observations (discussed below).

Since our ability to resolve strain changes improves at shorter periods, we can place better constraints on the largest precursive slip moment that might occur as a function of decreasing period or increasing resolution. At periods of seconds we can resolve 0.01 nanostrain, over hours it is 0.1 nanostrain and over weeks it is 1.0 nanostrain. Simple elastic dislocation calculations (Okada, 1985, 1992) allow us to calculate strains at these different levels for precursive slip moments at various depths. For example, a slip moment of 10^{12} N m at a depth of 5 km will produce surface strains of 0.01 nanostrain. If the depth is 8 km, the slip moment would be 3×10^{12} N m. Precursive slip moment as a function of resolution (or period) and depth is shown in Figure 14a.

How big might the nucleation zone be? Let us assume displacement, U , is proportional to rupture length, L . Observation and theory (constant stress drop assumption) support this assumption for earthquakes with M_L less than 6 (e.g., see Scholz, 1997). Then,

$$U = KL\Delta\sigma \quad (2)$$

where $K \approx 10^{-7}$ m MPa $^{-1}$ km $^{-1}$, L = rupture dimension, and $\Delta\sigma$ = stress drop (≈ 1 MPa). Therefore, the moment M is given by:

$$M \approx \mu 10^{-4} L^3 \quad (3)$$

where μ is the rigidity. It is thus possible to obtain crude limits on the nucleation size since we have limits on the maximum precursive slip moment that can be released over periods of weeks to seconds before seismic rupture. Figure 14b shows the equivalent limit on the source zone size obtained from Eq. (3) as a function of resolution (or period) and depth. For the $M = 5$ earthquakes at Parkfield, where we are within 7 km of the source, the maximum size of the nucleation patch in the last few seconds before seismic radiation occurs, is about 69 m. At longer periods, where the resolution is less, the constraint on size becomes poorer. On time periods of several weeks where our capability to resolve strain changes is not more than a few nanostrain, we cannot resolve nucleation regions unless their dimensions are greater than several hundred meters. However, it is important to note that, in the last hours to seconds before rupture, we would expect the largest nonlinear strain

FIGURE 12 (a) Strain time histories from strainmeters FR and DL on opposite sides of the San Andreas fault from 15 to 26 Dec. 1994. Full-scale on the upper plot is 200 nanostrain that on the lower plot is 10 nanostrain. (b) Expanded time-history at 10:27 UT on 20 Dec. 1994. The upper plot shows the strain seismogram of the $M=5.0$ earthquake starting at about 10:27:49 UT. The lower plot shows an even more expanded section during the 2 sec before the first arrival. The strain units on the vertical scale are 1000 nanostrain. (c) Expanded vertical scale for the time-history at 10:27 UT on 20 Dec. 1994 shown in (b) (lower). The upper plot shows the vertical scale expanded by 100 and the lower plot shows the scale expanded by 10 000. The actual occurrence time is shown with a vertical arrow. Similar data were obtained for the other two $M=5$ earthquakes on these instruments.

(as indicated in Fig. 1). It is during this time period that strain resolution is the best. The fact that no clear indication of accelerating strain is apparent in any of the strain records suggests nucleation patch sizes of perhaps a few tens of meters. Repeating microearthquakes on patches with this dimension have been observed by Nadeau and McEvilly (1997).

These data similarly constrain changes in pore pressure in the fault zone that may be related to the failure process. If we assume no hydraulic connectivity between a region of high pore pressure on the fault zone (such as proposed by Byerlee,

1990, 1993) and ignore for the moment how pore pressure changes in these regions might occur, it is obvious from simple calculations of strain generated by changes in pore pressure for regions with dimensions of a few hundred meters and depths of about 5 km that rapid changes in pore pressure of 0.1 MPa should be readily detected, though not necessarily recognized as such. If hydraulic communication with the surroundings does exist, smaller pore pressure changes might be detected as poroelastic strain as fluids diffuse out to greater distances, in effect increasing the source size. Small changes

FIGURE 13 Plot of maximum possible prerupture moment as a percentage of the seismically determined moment for the events studied listed in Table 1. Closed circles show data obtained within one rupture length of subsequent earthquakes. Open circles show data obtained at greater distances.

in the local geometry of regions with high pore pressure such as, for example, a 100 m by 100 m zone at 5 km depth dropping pressure by doubling its size probably would not be detectable.

It is also apparent in these data that large-scale changes in elastic properties within the fault zone are not occurring near these instruments. If they were, we would expect changes in tidal shear strain and volumetric strain response. Observations of earthtide response before and after the largest earthquakes (Landers, Loma Prieta, etc.) indicate that if measurable changes occur, they are less than 1% (Linde *et al.*, 1992).

5.2 Comparison with Laboratory Observations

It seems unlikely that both the wealth of laboratory data describing anelastic deformation of unfractured crustal rocks before failure and theoretical calculations of anelastic deformation during crack initiation and crack behavior are not relevant to initiation of fault failure. However, it is clear from existing surface and borehole strain data that slip instability over the entire subsequent fault rupture is not possible unless the time constant for rupture initiation is unrealistically short or prerupture deformation is exceedingly small. Laboratory measurements of crustal rocks under high confining pressure indicate anelastic strains before failure are comparable to the elastic strain release upon failure (Jaeger and Cook, 1976). On the other hand, frictional slip on preexisting slip surfaces in large-scale laboratory friction experiments (Dieterich, 1981) indicates nucleation slip does initiate within a small nucleation

FIGURE 14 (a) Maximum nucleation moment release allowable as a function of nucleation source depth for strainmeter resolution in nanostrain at different periods. Over periods of seconds the resolution is 0.01 nanostrain, over periods of hours it is 0.1 nanostrain and over periods of weeks it is 1 nanostrain. (b) Maximum nucleation zone size allowable as a function of nucleation source depth for strainmeter resolution in nanostrain at different periods. Over periods of seconds the resolution is 0.01 nanostrain, over periods of hours it is 0.1 nanostrain and over periods of weeks it is 1 nanostrain.

region. Dieterich (1992) shows numerical calculations that indicate the size of these regions should be 1–10 m for both smooth or rough initial stress distributions, consistent with the upper bounds allowed by the strain data. It would appear from

both data that the scale on which rupture initiates is several orders of magnitude smaller than that of the subsequent earthquake. If so, the fault model relevant to this process must be inhomogeneous in character to accommodate these observations that crustal failure does not occur simultaneously across the entire rupture zone, but is apparently triggered by failure of small localized zones.

Comparisons can also be made to the duration of nucleation derived by Dieterich (1994), who determined an expression for the time to failure during nucleation as a simple function of sliding velocity. For reasonable values of stiffness, velocity, normal stress gradient, etc., the duration of nucleation is on the order of 1–10 sec. This is in general agreement with the indications from the strain data. Furthermore, the nucleation moment from these laboratory measurements (Dieterich, 1992) is also only a small fraction of the slip moment as seen in the strain data.

5.3 Comparison with Current Theory

That an inhomogeneous faulting model may best describe the initiation of failure is not at all surprising. Wyss and Brune (1967) and many researchers since then have made similar suggestions. Based on careful analysis of seismic waveforms and on synthetic waveform generation, Kanamori (1981) and Lay *et al.* (1982) have shown that an inhomogeneous rupturing model is required to explain the complex waveforms generated by many large earthquakes. These data have been used to suggest that regions of greater strength (barriers or asperities) can be broken during fault failure and energy release from these regions contributes to the seismic radiation.

Inhomogeneous fault models have been proposed by McGarr (1981) to explain peak ground motion in an earthquake, by Dieterich (1986) to explain simulated faulting in laboratory samples, and, in a more general way, by Rundle *et al.* (1984) to explain seismicity gaps, fault roughness indicated by complex seismic waveforms, and apparent triggering effects. The data reported here are consistent with the suggestion outlined above that rupture initiation most likely occurs at smaller regions of higher strength which, when broken, allow runaway catastrophic failure. An inhomogeneous failure model, in which various areas of the fault plane have different stress-slip constitutive laws, appears necessary to explain both the processes that lead to failure and those that occur following failure. This type of model was proposed by Rundle *et al.* (1984). Other inhomogeneous failure models are also possible.

6. Conclusions

Observations of crustal strain at high sensitivity near active faults allow us to identify the main features of strain transients

that occur. On timescales of years, the primary features are uniform strain accumulation with occasional strain steps generated by large earthquakes, followed sometimes by post-seismic strain redistribution (Savage, 1983; Burgmann *et al.*, 1997). Conventional geodetic, EDM instruments and GPS instruments are best used to obtain these data. At shorter timescales (months to milliseconds), higher strain resolution is possible either by spatial averaging with a laser interferometer over about 500 m to suppress surface noise (Wyatt, 1988), or by installing instruments at depth in boreholes (Sacks *et al.*, 1971; Gladwin, 1984).

Strain transients associated with fault creep events indicate that these events result primarily from near-surface soil failure that is driven by deeper smoother fault slip. These events can sometimes be triggered by high accelerations during the passage of seismic waves from large nearby earthquakes (Simpson *et al.*, 1988) and sometimes by rainfall (Schulz *et al.*, 1982). In either case the event-like character is not of much interest in fault mechanics. However, the net creep-time history does appear to reflect the net slip on the fault and long-term changes in fault creep rate are important indicators of change in fault slip rate at depth.

There is little evidence of slip waves propagating slowly along active faults, at least on timescales of months to minutes. Either the amplitudes of these slip waves, if they exist, is very small (≤ 1 cm), or the period is so large that they cannot be resolved from the longer-term noise. Even at long periods (month to years), evidence of slip waves is not apparent in 2-color EDM data at Parkfield and San Juan Bautista where periodic surface displacements on opposite sides of the San Andreas fault of a millimeter or so should be readily detectable. The resolution of the 2-color EDM is about 0.1 mm (Langbein, 1981).

Coseismic strain offsets recorded on borehole strainmeters for earthquakes with magnitudes from 3 to 7 are generally in good agreement with offsets expected from simple dislocation models of these earthquakes. This suggests that the use of dislocation models for calculating coseismic stress changes (e.g., Reasenber and Simpson, 1992) is generally valid, or at least far removed from the rupture ends. The variable and general amplified coseismic offset response to earthquakes previously observed in the cracked and fractured material near the Earth's surface, and in caves or tunnels, appears to be avoided by installing instruments in grout in deep boreholes. An important implication of these observations is that strain redistribution from an earthquake is transmitted largely elastically through the complex geology and fault geometry in these regions. A second important implication is that preliminary moment determinations can be made within a few tens of minutes of the occurrence of moderate magnitude earthquakes from observation of the strain offsets generated by these earthquakes.

Unambiguous strain recordings on several borehole strainmeters now exist of several slow earthquakes on the

San Andreas fault near San Juan Bautista and other locations. The clearest event occurred on a 6 km long by 8 km wide segment of the fault just to the north of San Juan Bautista during a 4-day period starting on 11 Dec. 1992. This event is complex with a number of episodes. Evidence exists for both slip acceleration and variable slip geometry for these episodes. This event and later events in 1996 and 1998 are unique in the 15-year record of strain at these sites. The 1992 event generated shear-strains exceeding 1 microstrain on the tensor strainmeter MSJS near the town of San Juan Bautista and dilatational strain exceeding 0.7 microstrain at the dilatational strainmeter SRLS 5 km to the northwest along the fault. A third dilatometer installed some 7 km from the fault recorded strains of about 0.1 microstrain. Quasi-static modeling of this event indicates that it probably ruptured a 50 km² segment of the fault in less than 10 min and that episodes of exponential-like slip, either triggered or accelerated by the larger aftershocks, continued with time. Nearly four days after the event started at depth, it reached the surface and generated a 3-day episode of surface fault displacement that was recorded on a surface creepmeter XSJ2 east of the town of San Juan Bautista. The entire sequence generated event moment release that was equivalent to a $M = 5$ earthquake.

Actual recordings of slow earthquakes have been rarely reported in the geophysical literature. The question naturally arises as to whether this is because they are truly rare, or whether the situation has resulted from the paucity of high-sensitivity strain instruments installed near active faults and the relatively short history of high-quality recordings. In any case, as a consequence of these slow earthquakes near San Juan Bautista, the immediate likelihood of moderate magnitude earthquakes in this region has been reduced, in contrast to suggestions by Behr *et al.* (1990).

Popular views of the Earthquake nucleation process and fault kinematics have included suggestions of nonlinear deformation prior to rupture in regional-scale "preparation zones" of earthquakes (Rice and Rudnicki, 1979), strain redistribution by "crustal block interaction" (Jackson and Molnar, 1990), propagating aseismic slip waves (Kasahara, 1979), and variation in the material properties of near-fault materials with time and location (Dobrovolsky *et al.*, 1979).

In contrast, attempts to detect preseismic strain change near several recent moderate earthquakes during the final hours to seconds approaching rupture near many moderate earthquakes in California and Japan have failed. This places important constraints on possible moments and dimensions of nucleation events. First, since short-term nonlinear precursive strains greater than a nanostrain have not been observed in the eventual epicentral region prior to rupture, moment release during nucleation is thus ≈ 300 times smaller than that released statically and $\approx 10,000$ times smaller than that released dynamically. For the best cases investigated, the greatest possible preseismic moment is less than 0.1% of the final seismic or

geodetic moment. This implies tertiary creep prior to rupture is minimal over the entire eventual rupture zone, as expected for brittle failure.

Secondly, the dimensions of the rupture nucleation region for the largest earthquakes for which we have high-resolution near-field preseismic strain data, are less than several tens of meters. This is consistent with nucleation dimensions suggested by clusters of repeating microseismicity (Nadeau and McEvilly, 1997) and with indications from earthtidal response that fault zone material properties are invariant on timescales of days to months (Linde *et al.*, 1992).

The apparent small size of the rupture initiation moments compared to the total earthquake moments suggests that there is no scaling of the nucleation process with earthquake magnitude. This is inconsistent with suggestions by Ellsworth and Beroza (1995) and Iio (1995) that nucleation scales with earthquake magnitude. In fact, one of the earthquakes used by Ellsworth and Beroza (1995) to demonstrate nucleation is the one shown in Figure 12. The strain data require no processing, have a flat response from 50 Hz to DC and show no indication of nucleation prior to the first seismic wave arrival. The basic failure process thus apparently involves rupture nucleation and runaway. High pore pressure fluids may be associated with this process but if pore pressure changes drive the nucleation process, these changes are less than about 0.1 MPa at seismogenic depths.

An inhomogeneous faulting model for which different areas of the fault plane have either different constitutive properties or different stress-slip constitutive laws most easily explain these data. This type of model was proposed by Rundle *et al.* (1984) and is indicated by observations of complex seismic waveform generation during rupture (Kanamori, 1981; Lay *et al.*, 1982). For these inhomogeneous models, failure initiation occurs in relatively localized zones and expands until barriers of sufficient strength to stop the rupture, are encountered. The processes that lead to failure as well as those that follow failure are inhomogeneous in character. Energy driving the system appears to come from uniformly accumulated elastic strain energy (Prescott *et al.*, 1979). Detection of rupture nucleation apparently will require these highly sensitive and stable instruments be installed even closer than at present to the hypocenters of large earthquakes.

A variety of postseismic responses have been observed. This mostly reflects continuing slip following large earthquakes, with contributions in some cases from the equilibration of the fluid regime. During this postseismic period, slip varies as log (time) consistent with either relaxation of a near-surface region after stress-induced velocity strengthening (Scholz, 1990), or a fluid-diffusion process. Afterslip is common in regions where aseismic fault slip occurs, such as on the San Andreas fault following the 1966 Parkfield earthquake (Smith and Wyss, 1968), and on the Imperial fault following the 1979 Imperial Valley earthquake (Langbein *et al.*, 1983).

Acknowledgments

Numerous colleagues have provided stimulating discussions. We thank Bob Mueller and Doug Myren for help with installation and maintenance of the strain instruments and John Langbein for contributions to Figure 2. Ruth Harris and Nick Beeler provided thoughtful reviews.

Estimating Earthquake Source Parameters from Geodetic Measurements

Kurt L. Feigl

Centre National de la Recherche Scientifique, Toulouse, France

1. Brief Summary of Applicable Techniques

Figure 1 sketches the geometry of the various geodetic techniques for coseismic surveying. I will emphasize the new INSAR technique because the older techniques have been described well elsewhere and the newer SLR, VLBI, and DORIS techniques apply only to a few earthquakes.

FIGURE 1 Sketch of geometry for various geodetic techniques.

1.1 Ground-based Vertical Techniques

Spirit leveling measures the difference in elevation between pairs of points. Errors accumulate with the square root of the length L of the “line” (almost always a road) between the points. Typical first-order leveling measurements have a standard deviation of the order of $L^{1/2}$ mm with L in km, i.e., ~ 10 mm over 100 km (Bomford, 1980). Bilham (1991) reviews geophysical applications of this technique.

Leveling measures heights with respect to the geoid (or “mean sea level”). Such “orthometric” heights are not to be confused with the “ellipsoidal” heights provided by some GPS instruments. The difference between the two is typically of the order of 10 m, and represents the undulation of the geoid. In the excitement immediately following an earthquake, scientists often consider remeasuring an old leveling line with GPS. Although this approach will not measure coseismic displacements, it can detect a different quantity — the geoid (Milbert and Dewhurst, 1992; Calais *et al.*, 1993).

Leveling is the ground-based technique of choice for measuring vertical coseismic displacements larger than about a centimeter. It seems to work best for normal-faulting events with magnitude of 6 or larger where surface rupture creates a spectacular offset, for example, the 1983 Borah Peak earthquake (Stein and Barrientos, 1985; Ward and Barrientos, 1986). Leveling data can also provide useful information in thrusting events without surface rupture, such as the 1989 Loma Prieta earthquake (see references in Table 1).

Sea level as recorded by tide gauges can also reveal vertical coseismic motion, as in the great 1964 Alaska earthquake (Holdahl and Sauber, 1994) (see Bilham (1991) for a review). If the coseismic motion is upwards on a coastline, it will kill mollusks by removing them from the water. Their new position above sea level records the vertical displacement with

a precision of the order of a decimeter, as in two Chilean earthquakes (Barrientos and Ward, 1990; Ruegg *et al.*, 1996). This “natural tide gauge” is the only way other than mapping surface rupture to measure coseismic displacements without planning an observation before the earthquake.

1.2 Triangulation and Trilateration Surveying

Triangulation measures the angle between two benchmarks as seen from a third with a precision of $4 \mu\text{rad}$ at best (Bomford, 1980). Now classic, this technique nonetheless established the relative positions of the vast majority of benchmarks in most national geodetic networks. For many earthquakes, these measurements are the only ones acquired before the earthquake, for example the great 1906 San Francisco earthquake (Thatcher, 1974; Matthews and Segall, 1993; Thatcher *et al.*, 1997) and other studies in California (Savage and Burford, 1970).

Trilateration measures the distance between two benchmarks with a precision of the order of a centimeter (Bomford, 1980). For earthquake studies, its use seems to be limited mostly to California (Prescott *et al.*, 1979), although an early study in the Afar revealed over 2 m of displacement (Ruegg *et al.*, 1979).

Both triangulation and trilateration require a clear line of sight between the benchmarks, limiting their use to distances typically less than 30 or 50 km at most. As a result, many benchmarks were installed on hilltops and mountain tops with difficult access, the most extreme examples being the peaks in the High Karakoram (Chen *et al.*, 1984) and even the summit of Mt. Everest (Bilham, 1998). This offers the advantage of conserving the benchmark from destruction for long periods of time. Interestingly, many of these older benchmarks on summits continue to serve because they also provide an unobstructed line of “sight” to orbiting satellites. Also, these rocky summits provide more stable monuments than do boggy lowland soils.

1.3 VLBI

Very Long Baseline Interferometry (VLBI) measures the position of radio antennas with respect to radio sources in quasars (Smith and Turcotte, 1993). Although capable of sub-millimeter precision in relative position vectors (Herring, 1992), this technique requires large (~ 10 m) antennas. As such, it has only measured coseismic displacements for a few earthquakes: Loma Prieta, California (Clark *et al.*, 1990), and the 1987–1988 Gulf of Alaska earthquakes (Saubert *et al.*, 1993).

Nonetheless, VLBI supports earthquake studies by contributing important geometric information to the definition of geodetic reference systems such as the International Terrestrial Reference Frame (ITRF) (Sillard *et al.*, 1998).

1.4 SLR

Satellite laser ranging (SLR) measures the round-trip distance between an instrument on the ground and a reflective, massive, spherical satellite in low (500–1200 km altitude) orbit. The measurement uncertainty is typically 7 cm in distance, which implies subcentimeter uncertainties in all three vector components of relative position between two benchmarks (Tapley *et al.*, 1993). Since SLR instruments are many times heavier than for GPS, they are usually deployed at astronomic observatories, with the exception of a few mobile instruments deployed in California under the auspices of NASA's Crustal Dynamics Program (CDP) (Smith and Turcotte, 1993) and in the Mediterranean region under the WEGENER program (Smith *et al.*, 1994; Noomen *et al.*, 1996). In both of these networks, most of the SLR measurements useful for tectonic studies occurred in the late 1980s and have been largely supplanted by GPS in the 1990s. As a result, I could not find a published example of a coseismic displacement recorded by SLR.

1.5 GPS

The Global Positioning System (GPS) can provide subcentimeter estimates of relative position using an instrument available for less than “10 kg, 10 W, and 10 \$K.” Since the most precise solutions involve postprocessing data from multiple instruments, it typically requires several days between acquisition and estimate. The constellation of satellites came into use gradually beginning in 1985; it became fully operational in 1992. Data from this early period are typically more difficult to analyze and may yield less precise results than more recent surveys. For reviews of geophysical applications, see Dixon (1991), Hager *et al.* (1991), Hudnut (1995), Larson (1995), and Segall and Davis (1997). For earthquake studies, GPS networks tend to operate in one of two end-member modes: continuous operation of permanently installed, widely spaced antennas (CGPS), or intermittent occupation of densely spaced benchmarks in “campaign” mode. The former offers good temporal resolution (1 measurement/30 seconds = 33 mHz) but poor spatial resolution (>100 km between stations), whereas the latter offers poor temporal resolution (1 measurement/year = 32 nHz) and good spatial resolution (~10 km between stations). This trade-off between temporal and spatial resolution creates a difficult decision in the face of limited resources. Although a compromise “hybrid” strategy could rotate expensive receivers on a roughly monthly basis through several fixed monuments, this approach has yet to be

FIGURE 2 Tradeoff between poor spatial resolution and high cost in a GPS network designed to cover an area $a^2 = 1000$ km by 1000 km with n instruments spaced d km apart implies that $d = a/n$. Permanently deploying one receiver at each benchmark in the network in the “classic” approach (solid line) costs more than rotating each receiver through (say) four sites in the “hybrid” approach (dashed line).

deployed, apparently because it requires more manpower than do permanent installations (Fig. 2).

1.6 DORIS

Détermination d'Orbite et Radiopositionnement Intégré par Satellite (DORIS) is a Doppler satellite navigation system developed by the French Space Agency (Lefebvre *et al.*, 1996). Designed for tracking satellites in orbit, this system currently flies on three satellites (SPOT2, SPOT4 and Topex/Poseidon). It resembles GPS with three important differences. First, the transmitter is on the ground, not on the satellite. Second, the current design of the space-borne receiver cannot track more than three instruments on the ground within a radius of 1000 km, although this restriction was relaxed with a new design launched aboard Jason in 2000. Third, the current DORIS tracking network covers the globe quite well, with at least one station on each of the 11 lithospheric plates.

These differences imply that DORIS is better suited to measuring plate motions at the global scale than is GPS, which still suffers from a lack of long-term stations in the southern hemisphere. For this application, multiyear time series of DORIS data can determine absolute velocities with uncertainties of $1\text{--}2\text{ mm y}^{-1}$ in horizontal components (Crétaux *et al.*, 1998).

On the other hand, DORIS is less well suited to local studies of earthquakes and faulting at scales shorter than 1000 km than is GPS, although the station at Sakhalin did capture the 1994

earthquake in Kamchatka (A. Cazenave, personal communication, 1999).

1.7 SAR Interferometry

This geodetic technique calculates the interference pattern caused by the phase difference between two images acquired by a space-borne synthetic aperture radar (SAR) at two distinct times. The resulting interferogram is a contour map of the change in distance between the ground and the radar instrument. Each fringe represents a range change of half the wavelength. Thus, the contour interval is 28 mm for C-band radars such as ERS and RADARSAT and roughly four times larger, 125 mm for the L-band JERS satellite. These maps provide an unsurpassed spatial sampling density (~ 100 pixels km^{-2}), a competitive precision (~ 1 cm) and a useful observation cadence (1 pass/month), as described in a review article by Massonnet and Feigl (1998), which is paraphrased here.

To capture an earthquake, INSAR requires three data sets: a SAR image before the earthquake, one after, and topographic information. The SAR images themselves are rich data sets well documented in the remote sensing literature (Curlander and McDonough, 1991; Henderson and Lewis, 1998).

The topographic information is necessary to model and remove the interferometric fringes caused by topographic relief as “seen in stereo” from slightly different points of view. To handle the topographic contribution, we can choose between the “two-pass” approach (e.g., Massonnet and Feigl, 1998) and the “three-pass” or “double-difference” approach (e.g., Zebker *et al.*, 1994). For earthquake studies, there is usually a trade-off between the two-pass approach, which requires a digital elevation model (DEM), and the three-pass approach, which requires a third SAR acquisition. Further discussion of relative merits of the two- and three-pass approaches are beyond the scope of this chapter.

To interpret an interferogram, one must understand how different effects contribute to the fringe pattern. Many instructive examples appear in review papers by Massonnet and Feigl (1998), Madsen and Zebker (1998) and Burgmann *et al.* (2000). The mathematical details appear in another review (Bamler and Hartl, 1998). Hanssen (2001) has written a thorough textbook. For earthquake studies, the most important effects involve topographic relief, orbital trajectories, and tropospheric refraction, usually in combination.

If the topographic information (a DEM for two-pass, or the “topo pair” in three-pass INSAR) is in error, the interferogram will contain artifactual fringes. They appear in the same location in every interferogram produced using that topographic model. To quantify this effect, Massonnet and Rabaute (1993) define the altitude of ambiguity h_a as the shift in altitude needed to produce one topographic fringe. Indeed, this parameter is inversely proportional to the perpendicular component of the (“baseline”) vector separating the two orbital trajectories,

conventionally written $B_{\perp}$, pronounced “B-perp,” and given in meters (Zebker and Goldstein, 1986). The number of “topographic” fringes is proportional to $B_{\perp}$ and inversely proportional to h_a . Thus we seek pairs of orbital trajectories with a small separation, that is, with *small* (absolute) values of $B_{\perp}$ and *large* (absolute) values of h_a for earthquake studies. It turns out that for the ERS satellites, an acceptably good orbital pair has both $B_{\perp}$ and h_a approximately equal to 100 m.

A topographic error of ε meters in the DEM will produce a phase error of ε/h_a fringes in the resulting interferogram. Errors in typical DEMs range from 10 to 30 m (Wolf and Wingham, 1992), implying that choosing a pair of images with $|h_a|$ between 20 and 60 m will yield an interferometric measurement with an error better than $\varepsilon/h_a = \pm 1/2$ cycle, or ± 14 mm for ERS. Small values of $|h_a|$ can mask even large signals with artifactual topographic fringes. In an extreme (and rare) case, Massonnet and Feigl (1995a) uncovered a topographic error of $\varepsilon \sim 250$ m, roughly 8 times larger than the published precision for the DEM. This artifact resembles the fringe pattern produced by a small earthquake. Avoiding such confusion requires looking at several interferograms with different values of h_a . For an earthquake, the number of coseismic fringes does not depend on h_a .

Atmospheric effects can also complicate the interpretation of an interferogram. Indeed, variations in the refractive index of the troposphere are the current limiting source of error in the INSAR technique (Goldstein, 1995; Massonnet and Feigl, 1995a; Rosen *et al.*, 1996; Tarayre and Massonnet, 1996; Zebker *et al.*, 1997; Hanssen, 2000). Potentially, one could confuse a topographic signature with a displacement, if propagation effects create fringes which “hug” the topography like contour lines, but which measure the change in tropospheric delay. This effect was first observed as several concentric fringes in a 1-day interferogram on Mt. Etna (Massonnet and Feigl, 1998; Beauducel *et al.*, 2000). One can recognize this subtle effect using pairwise logic (Massonnet and Feigl, 1995a) or using a DEM and local meteorological observations (Delacourt *et al.*, 1998; Williams *et al.*, 1998). However, separating the tropospheric noise from the deformation signal can be challenging, particularly when the signal is small, e.g., the magnitude 5.2 earthquake near St. Paul de Fenouillet, France (Rigo and Massonnet, 1999).

1.8 Correlation of Two Remote-sensing Images

It is also possible to detect (large) coseismic displacements by correlating two optical images. The “lag” vectors estimated between the corresponding subpixel cells of a prequake and a postquake image yields the horizontal components of the coseismic displacement vector with meter-level precision and hectometer resolution (Crippen, 1992; Crippen and Blom, 1992; Van Puymbroeck *et al.*, 2000). The same technique also applies to SAR images. By correlating two Single Look

Complex (SLC) SAR amplitude (“backscatter”) images acquired at different times, Michel *et al.* (1999) measured ground displacements for the Landers earthquake. Their result is “a two-dimensional displacement field with independent measurements every about 128 m in azimuth and 250 m in range. The accuracy depends on the characteristics of the images. For the Landers test case discussed in the study, the 1- σ uncertainty is 0.8 m in range and 0.4 m in azimuth. [They] show that this measurement provides a map of major surface fault ruptures accurate to better than 1 km and an information on coseismic deformation comparable to the 92 GPS measurements available. Although less accurate, this technique is more robust than SAR interferometry and provides a complementary information since interferograms are only sensitive to the displacement in range.” (Michel *et al.*, 1999.)

2. Estimating Earthquake Parameters by Inversion of Geodetic Data

2.1 The Standard Elastic Half-space Model

To explain the observed coseismic deformation, a simple model of a dislocation in an elastic half-space provides a good approximation. Indeed, it has become the conventional model used in most of the case studies considered here. Okada (1985) derives the expressions for the coseismic (permanent) displacement u at the Earth’s surface caused by a fault at depth in closed analytic form. Accordingly, the displacement field $u_i(x_1, x_2, x_3)$ due to a dislocation $\Delta u_j(\xi_1, \xi_2, \xi_3)$ across a surface Σ in an isotropic medium is

$$u_i = \frac{1}{F} \int_{\Sigma} \int \Delta u_j \left[\lambda \delta_{jk} \frac{\partial u_i^n}{\partial \xi_n} + \mu \left(\frac{\partial u_i^j}{\partial \xi_k} + \frac{\partial u_i^k}{\partial \xi_j} \right) \right] v_k d\Sigma \quad (1)$$

where δ_{jk} is the Kronecker delta, λ and μ are Lamé’s coefficients, v_k is the direction cosine of the normal to the surface element $d\Sigma$, and the summation convention applies. The term u_i^j is the i th component of the displacement at (x_1, x_2, x_3) due to the j th direction point force of magnitude F at (ξ_1, ξ_2, ξ_3) . For the complete set of equations see Okada (1985), who also corrects previous derivations. A public-domain computer program performs these calculations (Feigl and Dupré, 1999). Called RNGCHN, this program is included on the Handbook CD-ROM under the directory \37Feigl. Okada (1992) performs this calculation at any point in the half-space.

2.2 Fault Parameters

Here I follow Okada’s (1985) notation, as in Feigl and Dupré (1999). To describe a single fault element (also called a “sub-fault” or “patch”) as a dislocation requires ten parameters. The

fault patch has length L and width W . The slip on the fault plane is a vector $\mathbf{U}$ with three components, U_1 , U_2 , and U_3 . The position coordinates of the fault patch are E , N , and d , taken positive east, north, and down. The azimuth α gives the strike of the fault, in degrees clockwise from north. Finally, an observer facing along strike should see the fault dip at δ degrees to his right.

The Okada parameters differ slightly from the parameters favored by seismologists. In particular, the origin of Okada’s fault patch does not coincide with the centroid at the geometric center of the fault rectangle (Feigl and Dupré, 1999). For a double-couple source, the tensile component vanishes ($U_3 = 0$) and the slip vector $\mathbf{U}$ lies in the fault plane. Seismologists define the rake angle r such that $\tan r = U_2/U_1$ (Aki and Richards, 1980). Inversely, $r = \text{ATAN2}(U_2, U_1)$ where ATAN2 is the usual FORTRAN intrinsic function for arctangent (U_2/U_1) on the range $[-180^\circ, +180^\circ]$. A thrust-faulting mechanism, for example, has $U_2 > 0$ and $r > 0$. A normal faulting mechanism, on the other hand, has $U_2 < 0$ and $r < 0$. Similarly, left-lateral slip implies $U_1 > 0$ and $|r| \leq 90^\circ$, whereas right-lateral slip implies $U_1 \geq 0$ and $|r| \geq 90^\circ$.

2.3 Underlying Assumptions

The standard Okada model assumes that the Earth’s surface is flat, corresponding to the bounding plane of the elastic half-space. The Lamé coefficients λ and μ specify the elastic medium. For simplicity, most studies assume that $\lambda = \mu$, so that these parameters drop out of the expressions for surface displacement. Such a medium, called a Poisson solid, has a Poisson’s ratio of 1/4, a reasonable approximation to the values of 0.23–0.28 estimated from P - and S -wave velocities in the upper crust (Perrier and Ruegg, 1973; Dziewonski and Anderson, 1981). The so-called “geometric moment” or “potency” simply equals ULW . To obtain the seismic moment, multiply by the shear modulus μ so that $M_0 = \mu ULW$. Typical values (assumed) for μ in the Earth’s crust range from 30 to 36 GPa, but values as low as 10 GPa (Dal Moro and Zadro, 1999) and as high as 50 GPa (Barrientos and Ward, 1990) have been used. The simplest assumption takes this value to be constant throughout the half space, although some authors propose increases with depth (Dolan *et al.*, 1995; Cattin *et al.*, 1999). Some authors call μ the “rigidity,” whereas others use μ to denote a dimensionless coefficient of friction. To convert moment into the various magnitude scales, use the conventional formulas (Hanks and Kanamori, 1979; Abe, 1995). Empirical relations exist for establishing the size (L , W , and U) of the earthquake from the seismological magnitude or moment (Scholz, 1990; Dolan *et al.*, 1995).

2.4 Particularities of Geodetic Data

Like seismograms, geodetic measurements decompose the displacement vector into components. Although VLBI and GPS both record three components of the coseismic displacement

vector (postquake minus prequake position) of a benchmark, INSAR records only the component along the line of sight between the satellite and ground point. Image correlation provides the same line-of-sight (range) component as well as a second component parallel to the satellite trajectory (azimuth). The line of sight between the point on the ground and the radar satellite in the sky defines two angles, the radar incidence (from vertical) and the azimuth of the satellite ground track (from North). For the ERS satellites in California, for example, these quantities are approximately 23° and 13° , respectively. These quantities determine the unit vector $\hat{s}$ which points from ground to satellite. Then the change in range $\Delta\rho$ or the distance measured along the line of sight between the satellite and ground point is

$$-\rho = \mathbf{u} \cdot \hat{s} \quad (2)$$

Note that the sign convention is such that an upward movement will produce a positive value of $\mathbf{u} \cdot \hat{s}$, a decrease in range, and a negative value of $\Delta\rho$. The ray specified by $-\hat{s}$ is sometimes called the “look vector.” INSAR can provide a second component of the coseismic displacement vector if the satellite acquires two images in both the “ascending” (south-to-north) and “descending” (north-to-south) orbital passes. In this case, the east, north, and upward components of the unit vector $\hat{s}$ are $[x, y, z]$ and $[x, -y, z]$, respectively. To use the radar interferograms as data in an inverse problem requires an unambiguous measurement of the range change, which implies “unwrapping” the interferogram. See Ghiglia (1998) for a review of the techniques involved. For the Landers and Fawnskin earthquakes described below, we simply count and digitize the fringe pattern. Although tedious, this technique avoids errors because the human eye is very good at following colored fringes, even where they are noisy. It also recognizes areas where the fringes become too noisy to count. For the Eureka earthquake, a straightforward algorithm (Tarayre, 1994) performed well because the fringes were clear and simple.

Even unwrapped, radar range changes are still only relative measurements. To make them absolute, we must identify the fringe corresponding to zero deformation. We can do this by trial and error (Feigl *et al.*, 1995), or explicit estimation (Wright *et al.*, 1999), choosing the additive constant which produces the smallest misfit to the observed interferogram. Usually, the null fringe intersects the fault plane.

2.5 Modeling by Trial and Error

The standard Okada model defines the relation between the earthquake source parameters and the geodetic measurements of surface displacement. The goal is to find the values of parameters which best fit the data. This inverse problem seeks to minimize the difference between the modeled displacement field and the one sampled by geodesy. The simplest procedure is trial and error, usually called “forward modeling.” We use

our best guess for the value of each parameter to calculate a synthetic displacement field. With some clues about the location, geometry, and magnitude of the earthquake, it is not difficult to find a simulation which looks like the observed displacement field. By repeatedly tuning the parameters, we can usually fit the data better than our first guess. This procedure provided the first approximation to the coseismic deformation in most of the studies listed in Table 1.

2.6 Estimating the Focal Mechanism

If we choose to estimate all ten parameters for a single fault patch, the problem is nonlinear because the surface displacement depends strongly on the fault geometry. The approach uses “numerical optimization procedures to determine the best-fitting dislocation surface or surfaces. The methods can generally be divided into two categories: those methods, such as nonlinear least squares or quasi-Newton methods, that make use of the first or second derivatives and Monte Carlo methods that do not require these derivatives,” as described by Segall and Davis (1997).

For the derivative-based methods, the RNGCHN program includes analytic expressions for the first derivatives. These allowed us to use an iterative linearized least squares procedure for the 1992 Fawnskin (Feigl *et al.*, 1995) and 1993 Eureka Valley earthquakes (Massonnet and Feigl, 1995b).

The Monte Carlo techniques have the advantage of avoiding local minima and furnishing realistic estimates of uncertainties, as shown for the Loma Prieta (Arnadottir and Segall, 1994) and Cape Mendocino (Murray *et al.*, 1996) earthquakes.

Mixing the two categories of optimization methods in a hybrid, Monte-Carlo, downhill simplex scheme also works (Clarke *et al.*, 1996, 1998; Wright *et al.*, 1999).

2.7 Surface Rupture by Earthquake Faulting

By definition, a mapped fault is a discontinuity separating two blocks of the Earth’s crust. If the fault is active, the relative motion (slip) between the two blocks offsets the interferometric fringe pattern. Thus, surface rupture appears as a discontinuity in an interferogram, except where the slip vector is orthogonal to the radar look vector. Offsets as small as a centimeter tear the fringe patterns at Landers (Massonnet *et al.*, 1994; Price and Sandwell, 1998), Hector Mine (Sandwell *et al.*, 2000), and in the South Iceland Seismic Zone (Feigl *et al.*, 2000).

2.8 Fault Slip

Once we know the geometry of the fault, we can estimate the distribution of the slip vector $\mathbf{u}$. This inverse problem is linear. The components of the surface displacement $\mathbf{U}$ are proportional to the components of the slip vector $\mathbf{u}$. As such, it is simple to divide the modeled fault plane into many discrete patches. By varying only the amount of slip on each patch, but not its

geometry, we can estimate the distribution of slip on the fault plane. Numerous published examples of this procedure are listed in Table 1. Although most authors approach this problem using discrete fault patches, Bennett *et al.* (1994) use continuous functions. Comparing different solutions to this inverse problem is hindered by the lack of a single standard format for computer files. Worse still, very few authors publish the centroid of their estimate.

2.9 Moment

Geodetic observations of coseismic displacement are difficult to obtain because they require a measurement before the earthquake. Furthermore, such measurements are only possible at the Earth's surface. As a consequence, geodetic data sets tend to be sparse. To extract the most information from these data sets, we want to limit the number of free parameters in the optimization. Taken to the extreme, this approach suggests estimating only a single parameter – the moment – from the available data, as Johnson *et al.* (1994) do for the Landers earthquake.

2.10 Data Covariance Matrix

In solving these inverse problems, we expect to find a more reliable solution and a better estimate of the uncertainties if we account for the full covariance matrix, including the off-diagonal terms of the data. The Loma Prieta earthquake provides a case in point. There, Marshall *et al.* (1991) and Lisowski *et al.* (1990) applied standard least squares methods to the leveling and trilateration data, respectively, neglecting the off-diagonal elements of the data covariance matrix. As a result, they had to resort to a two-patch model to fit the geodetic data. This model came under fire because the second patch did not pass through the locus of aftershock hypocenters. By including the full covariance matrix, however, Arnadottir *et al.* (1992) were able to find an acceptable single-patch model which also fitted the aftershock distribution. The same authors later improved on their first model by allowing the slip to vary in a bootstrap Monte Carlo approach (Arnadottir and Segall, 1994).

Complete knowledge of the data covariance matrix is also necessary in joint inversions to weight the different types of data (Barrientos and Ward, 1990; Holdahl and Sauber, 1994).

3. Case Studies

3.1 Loma Prieta, California, 1989

In addition to revealing the importance of using the covariance matrix when inverting geodetic data, the Loma Prieta earthquake also focused attention on the issue of postseismic deformation. To fit the geodetic observations, Savage *et al.* (1994) proposed a model of “fault collapse” such that the

dislocation included a (negative) tensile component akin to reducing the volume of a rectangular prism or dike. Arnadottir *et al.* (1992) later concluded that the “geodetic data do not place useful constraints on the amount of dilatancy for this event,” a conclusion reaffirmed later (Bürgmann *et al.*, 1997).

3.2 Landers, California, 1992

Color Plate 14 shows INSAR results for the 1992 Landers earthquake. The slip distribution estimated from the radar data [shown in Plate 21 of Massonnet and Feigl (1998)] agrees qualitatively with those estimated from GPS survey measurements of coseismic displacements (Murray *et al.*, 1993; Freymueller *et al.*, 1994; Hudnut *et al.*, 1994), strong motion accelerations recorded in the near field (Cohee and Beroza, 1994; Cotton and Campillo, 1994, 1995), seismograms in the far field (Wald and Heaton, 1994), a joint inversion of all three data types (Wald and Heaton, 1994), and a combination of INSAR and strong motion data (Hernandez *et al.*, 1997, 1999). All these inversions find relatively little slip (2–3 m) below the epicenter where rupture began, but a maximum of 8–12 m of slip located at 5–10 km depth in the Homestead and Emerson fault segments between 30 and 40 km north of the epicenter. The depth and magnitude of the slip maximum seems to depend on the prior information in the various inversions. All the estimates agree on the seismic moment, in accord with the centroid moment tensor and the bounds estimated from the geodetic data (Johnson *et al.*, 1994).

The estimates of slip distribution contributed to calculations of coseismic stress changes which load the crust and thus trigger subsequent earthquakes (Harris and Simpson, 1992; Jaumé and Sykes, 1992; Stein *et al.*, 1992). By using a fine estimate of slip distribution estimated from several data sources (Wald and Heaton, 1994), Stein *et al.* (1994) predict aftershock locations better than with their original calculation (Stein *et al.*, 1992) which used only a coarse estimate of slip distribution based on GPS measurements alone (Murray *et al.*, 1993).

Both GPS and INSAR also measured postseismic deformation following this earthquake (Massonnet *et al.*, 1994; Shen *et al.*, 1994; Wyatt *et al.*, 1994; Massonnet and Feigl, 1995a; Massonnet *et al.*, 1996b; Peltzer *et al.*, 1996, 1998; Bock *et al.*, 1997; Savage and Svarc, 1997; Pollitz *et al.*, 2000), but these observations and the models needed to explain them exceed the limits of this chapter.

3.3 Eureka Valley, California, 1993

The Eureka Valley earthquake occurred on 17 May 1993 in a remote area of the Mojave Desert at the edge of the Basin and Range province. The normal-faulting $M_w = 6.1$ mainshock and subsequent aftershocks deepened the graben in an oval-shaped coseismic deformation field. The ERS-1 radar images are the only available geodetic measurements. This earthquake is an

interesting case study because two different approaches led to different interpretations. Massonnet and Feigl (1995b) calculate this interferogram by stacking two 2-pass interferograms in a combination of three radar images. Peltzer and Rosen (1995) analyze the same three images with the 3-pass technique. Both studies find approximately 10 cm of range increase.

To explain the observed fringe pattern, Massonnet and Feigl use an iterative least-squares procedure and the standard elastic dislocation model to estimate the earthquake focal mechanism. The best-fitting focal mechanism is a normal fault dipping $54^\circ \pm 2^\circ$ to the west and striking $S7^\circ W \pm 2^\circ$. The 16×7 km rectangular fault patch centered at 9 km depth does not cut the surface. The estimated geodetic moment magnitude of 6.1 agrees with the seismological estimates from wave-form inversion. The residual interferogram shows less than one 14 mm cycle in the difference between the observed and modeled fringes.

The location of the centroid estimated from the radar data is less than 6 km horizontally and 2 km vertically from the hypocenter estimated from *P*-wave travel times. The modeled fault patch, however, strikes more westerly than the mapped Quaternary fault or the fault plane estimated from first motions. Indeed, Peltzer and Rosen find that a fault plane striking $N7^\circ E$, dipping 50° west, but cutting the surface, provides a good fit to their radar interferogram, based on forward modeling. The fault patch estimated by Massonnet and Feigl resembles the locus of aftershocks in dip, length, width and horizontal location, but not depth.

The fault models also disagree about the depth of the slip, in particular, whether or not it breaks the surface. Peltzer and Rosen favor a variable-slip (multi-patch) fault model in which the uppermost fault patches cut the surface, while Massonnet and Feigl's optimized 1-patch model stops some 6 km short of the surface. Furthermore, Peltzer and Rosen observe an offset of approximately 3 cm in their interferogram, whereas Massonnet and Feigl see no such discontinuity longer than 1 km in their interferogram. Furthermore, Peltzer and Rosen observed a fault scarp with 1–3 cm of vertical displacement which they could follow in the field for a few tens of meters. Any surface rupture would have to be small, both in magnitude and spatial extent, to avoid cutting the fringes observed in Massonnet and Feigl's interferogram.

A small, shallow aftershock can explain all the observations and resolve the controversy. Some 3 cm of slip on a fault 1 km^2 in area represents an earthquake of magnitude 4. An earthquake of approximately this magnitude ($M_L = 3.5$) occurred at 0.02 km depth in this area. This location is also less than 1 km from the offset observed by Peltzer and Rosen, well within the uncertainties of the seismological estimates. Such an earthquake could have produced the short scarp observed by Peltzer and Rosen in the field. It could also produce concentric fringes 1 or 2 km in diameter in the interferogram. Two such fringes (28 mm of range) are

barely discernible near its epicenter in Massonnet and Feigl's interferogram.

3.4 Grevena, Greece, 1995

A $M_s = 6.6$ normal-faulting event in northern Greece illustrates the complexity of estimating source parameters from diverse data sets with different data types. The earthquake occurred near Kozani–Grevena on 13 May 1995, a decade after a triangulation survey, almost two years after the pre-quake ERS image, and 3–7 days before the field observations of centimeter-scale surface breaks. These observations form the basis of two separate analyses of the coseismic deformation which differ markedly both in their approaches and in their conclusions. Clarke *et al.* (1996) used GPS after the earthquake to measure 91 concrete pillars that had been surveyed prior to the earthquake by triangulation with formal uncertainties of 15 mm in horizontal relative position. Using a “hybrid simplex-Monte Carlo method which requires no a priori constraints,” they estimate the focal parameters for a single fault patch. Working separately, Meyer *et al.* (1996) used INSAR to calculate several coseismic interferograms. The best one spans almost two years and is only partially coherent. Using the INSAR results in conjunction with their map of surface rupture, tectonic maps of fault geometry, Meyer *et al.* (1996) determine a model with 22 fault patches.

The two models disagree substantially, leading to a critical exchange of comment (Meyer *et al.*, 1998) and reply (Clarke *et al.*, 1998). The GPS-derived model predicts coseismic INSAR range changes that disagree with the observed interferogram. Similarly, the INSAR-based model predicts coseismic displacements that disagree with the displacements observed by the GPS-triangulation comparison by more than several times their measurement uncertainty. There are several partial explanations for this discrepancy.

Firstly, the two studies invert data which sample the coseismic displacement field in different places. The INSAR coherence breaks down in several crucial areas: both where Meyer *et al.* could measure surface rupture and around many of the pillars where Clarke *et al.* measured large displacements. And the spatial distribution of the data makes a difference in the inversion procedure, as discussed below.

Secondly, the inversion procedure makes a difference, as described in the comment and reply. In particular, constraining the fault plane to pass through the mapped surface break can shift the fault plane significantly, particularly in the presence of irregularly sampled data.

This exercise of independent analyses of independent data sets raises several issues. First, that geodetic and seismological estimates of moment can differ significantly. Second, we still lack good ground-truth evaluations of surface breaks as measured by INSAR, which records them as discontinuities in the fringe pattern. Thirdly, the geometric

relationship between geodetically estimated fault planes, the mainshock location, and the distribution of aftershocks is not clear.

4. Synthesis and Conclusions

4.1 Depth Estimates

Several studies suggest that geodetic estimates tend to locate the coseismic slip at a shallower depth than seismological estimates of the mainshock hypocenter or centroid. There are several possible explanations for this discrepancy which became glaringly apparent for the Northridge earthquake (Hudnut *et al.*, 1995).

4.1.1 Rheological Inhomogeneity

For computational simplicity, most geodetic inversions assume an elastic half-space with a constant rheology throughout. Local heterogeneities in crustal rheology clearly violate this assumption. The half-space approximation is not even consistent with the simple layered models routinely used for locating earthquake hypocenters. In particular, if the assumed value of the shear modulus μ is too high, then the geodetic estimate will underestimate the depth, yielding a location which is too shallow (Cattin *et al.*, 1999). This shortcoming may also explain the observation that most of the aftershocks are near, but not on, the mainshock fault plane for Northridge (Hudnut *et al.*, 1995), Cape Mendocino (Murray *et al.*, 1996), and Antofagasta, Chile (Ruegg *et al.*, 1996). Thus Segall and Davis (1997) suggest that “it now seems probable that the effects of inhomogeneity, and perhaps anisotropy in the Earth’s crust can no longer be neglected (e.g., Du *et al.*, 1994).” A different solution to this problem allows layering in a spherical earth (Pollitz, 1996; Cummins *et al.*, 1998). The differences with respect to the half-space solution can be of the order of 10–20% at distances of 100–400 km from the source (Cummins *et al.*, 1998).

4.1.2 Nonplanar Fault Geometry

A normal fault which shallows with depth, as Meyer *et al.* (1996, 1998) argue for Grevena, is difficult to approximate with the simple model of a single, planar fault patch. Since the latter is the only feasible geometric parametrization in the nonlinear focal mechanism inverse problem, it may not pass through the mainshock hypocenter unless constrained to do so (Clarke *et al.*, 1996, 1998).

4.1.3 Irregular Distribution of Data

Geodetic networks with benchmarks on rock outcrops do not form regular grids. Even INSAR, which in principle samples the deformation on a regular grid, can break down in

certain areas, creating “blots” of missing data. For the Dinar earthquake, for example, all the usable INSAR data fall on the hanging-wall block (Wright *et al.*, 1999). Such an asymmetric distribution of data may tend to “pull” the modeled fault plane towards the data points.

4.2 Distribution of Slip and Aftershocks

The Landers studies show that aftershocks tend to occur near the parts of the fault plane where the amount of slip is small, e.g., Plate 21 of Massonnet and Feigl (1998) and Figure 13 of Cohee and Beroza (1994). In other words, aftershocks correlate spatially with the absence of slip. A similar, but weaker, correlation has also been observed for Loma Prieta (Arnadottir and Segall, 1994). It seems that slip may relieve stress on the fault patch where it occurs, but increase stress in the neighboring patches.

4.3 Geodetic Versus Seismological Estimates of Moment

Figure 3 shows that geodetic estimates of seismic moment tend to exceed seismological estimates by as much as 60%. Again, there are several possible explanations.

4.3.1 Measurement Interval

Geodetic measurements of relative position before and after the earthquake span a much longer period of time than does a seismogram and thus include more deformation, both interseismic and postseismic. Thus geodetic measurements sometimes include the moment released by aftershocks and/or afterslip, whereas the seismological estimate pertains only to the mainshock (Kanamori, 1973; Wyatt, 1988). Whereas historical geodetic measurements may impose an interval of several decades, satellite techniques can reduce the interval to a single 35-day orbital cycle in the case of the ERS satellites or to a single day or less in the case of continuous GPS. In this sense, geodesy, as ultralong period seismology, should follow the rule of thumb that moment estimates tend to increase with the measurement period.

4.3.2 Incorrect Shear Modulus

To convert seismic potency (in m^3) to moment (in N m) requires accurate knowledge of the shear modulus μ . Yet this parameter is rarely measured. Usually, it is assumed to take conventional values between 30 and 36 GPa, a range large enough to explain a 20% discrepancy. Of course, for a rigorous comparison, we should use the same value for the shear modulus μ in the (geodetic) dislocation model and in the (seismological) velocity model. In practice, however, this will require generalizing the dislocation theory to admit layering.

FIGURE 3 Comparison of seismic moment estimated from geodetic measurements $M_0^{(g)}$ and seismic moment estimated from centroid moment tensor solutions $M_0^{(s)}$. The vertical axis shows the ratio $\delta M = (M_0^{(g)} - M_0^{(s)})/M_0^{(s)}$ using the values in Table 1. The geodetic moment is larger than the seismic moment for most events.

4.3.3 Aseismic Deformation

Geodetic estimates of moment will include deformation caused by any phenomenon including creep, fluid injection, or even “silent” earthquakes. For example, the geodetic estimate derived from the 2 m of displacement measured for the 1978 Asal rifting event in the Afar region is 6×10^{17} N m, over three times larger than the 1.7×10^{17} N m estimated for the sum of the two largest $M = 5$ earthquakes (Lépine *et al.*, 1979; Ruegg *et al.*, 1979; Stein *et al.*, 1991).

4.4 Conjugate Faults

For earthquakes of intermediate magnitude, choosing between two possible focal planes is both challenging and interesting. For a point source observed from the far field, neither seismological analysis of first arrivals nor geodetic measurements of surface displacements can tell the difference because the two cases produce rigorously identical results. For example, a fault plane parallel to the subduction zone and a plane perpendicular to it both fit the large coseismic displacements observed by continuous GPS after the 1994 Hokkaido-Toho-Oki earthquake in Japan (Tsuji *et al.*, 1995).

For a dipping, finite fault with dimensions larger than the distance between geodetic observations, this ambiguity should fade as asymmetry begins to appear. In particular, the displacement vectors above the downdip edge of the fault are smaller than above the upper edge. In some cases, the RMS misfit is less than 1 mm better for one fault plane than for its conjugate (Stein *et al.*, 1991; Feigl *et al.*, 1995; Massonnet and

Feigl, 1995b). With good sampling, however, it is possible to identify the rupture plane (Hudnut *et al.*, 1995).

4.5 Utility for Assessing Seismic Risk

Since seismologic data yield good estimates of the slip distribution, why estimate it from geodetic data? In remote areas, strong-motion seismological instruments may not exist, whereas a satellite radar interferogram can provide true remote sensing. Second, geodetic surveys record deformation over a much longer period (several months), than the seismological record, revealing any slip which occurred before or after the mainshock rupture. Third, geodetic surveys can capture aseismic slip. Finally, accurate descriptions of the total slip distribution are useful for calculations of coseismic stress changes.

4.6 Future Prospects

To contribute more useful information to the understanding of earthquake source parameters, geodetic analyses should attempt to address the following issues.

4.6.1 Measurement Uncertainty for INSAR

We do not yet understand know the error budget for INSAR measurements. For sophisticated inversion schemes, we should account for the structure of the data covariance matrix. This issue becomes particularly important for joint inversions of different data types, such as INSAR with GPS, or strong-motion seismograms. I emphasize that correlations between data also

influence Monte Carlo-like algorithms, which often incorrectly assume independent, random errors.

4.6.2 Routine Application of INSAR

To date, several factors make INSAR measurements of coseismic deformation a hit-or-miss, opportunistic affair. For example, the lack of a good digital elevation model can inhibit the application of INSAR to earthquakes outside the US. This difficulty should be resolved by the Shuttle Radar Topography Mission flown in early 2000. Its data should lead to public distribution of a 90 m DEM by 2004. Similarly, the lack of closely spaced orbital trajectories can force compromises. This difficulty will be partially alleviated by ENVISAT, which will have better orbital control than ERS, JERS, or RADARSAT. Third, capturing earthquakes with INSAR is a major challenge because no-one knows where they will occur. This implies that each INSAR-capable satellite must acquire a catalog of prequake images over all the land areas likely to produce a measurable earthquake. I estimate this area to be of the order of 70 million km².

4.6.3 Joint Inversions

Geodetic data seem to help constrain seismological solutions at relatively long temporal periods (days to years) and intermediate spatial scales (within several fault dimensions of the rupture), as demonstrated for Landers by Wald and Heaton (1994). They inverted GPS measurements of coseismic displacements, strong motion seismograms and teleseismic wave forms, both jointly and separately. Including INSAR measurements in this type of inversion is likely to furnish interesting results, as suggested for Landers (Hernandez *et al.*, 1999) and Dinar (Wright *et al.*, 1999).

4.6.4 Related Phenomena

INSAR and CGPS open two new windows in the spatio-temporal spectrum of seismological metrology: INSAR at distance scales between ~1 and ~10 km; CGPS at timescales of days to years. Prior to the introduction of these two techniques, measurements at these scales were prohibitively expensive or prone to drift. Now that both techniques have entered the realm of operational, routine observations, we should expect to see interesting observations of other seismological phenomena, such as slow earthquakes, interseismic strain accumulation, and perhaps even an earthquake precursor.

Acknowledgments

Electromagnetic Fields Generated by Earthquakes

M.J.S. Johnston

US Geological Survey, Menlo Park, USA

1. Introduction

Independent knowledge of the physical processes that occur with seismic events can be obtained from observations of electric and magnetic fields generated by these complex processes. During the past few decades, we have seen a remarkable increase in the quality and quantity of electromagnetic (EM) data recorded before and during earthquakes and volcanic eruptions. This paper describes the most significant recent data and the implications these data have for different generating mechanisms. We note that, despite several decades of relatively high quality monitoring, clear demonstration of the existence of precursory EM signals has not been achieved, although causal relations between coseismic magnetic field changes and earthquake stress drops are no longer in question. This paper extends discussions of tectonomagnetism and tectonoelectricity, over the various parts of the electromagnetic spectrum from radio frequencies (RF) to submicrohertz frequencies, that are covered in Johnston (1989, 1997), Park *et al.* (1993), Park (1996) special journal issues (Johnston and Parrot, 1989, 1998; Parrot and Johnston, 1993), and books (Hayakawa and Fujinawa, 1994).

2. History

Suggestions that electromagnetic field disturbances are a consequence of the earthquake failure process have been made throughout recorded history. Some of the earliest work (Milne, 1890, 1894) refers to magnetic fields observed during the Great Lisbon earthquake in 1799. However, these early observations, and others during the nineteenth century (Mascart, 1887; Milne, 1894), were recognized as spurious by Reid (1914) who showed that traces recorded by magnetographs located close to earthquake epicenters were produced by inertial effects, not magnetic disturbances. This invalidated all earlier reports based on records of magnetic variometers, which are simply suspended

magnets. Later data up through the mid-20th century recorded on fluxgate magnetometers are similarly suspect because these instruments are sensitive to displacements and rotations common in the epicentral regions during the propagation of seismic waves. It was not until the mid-1960s that meaningful results were obtained following the advent of absolute magnetometers, use of noise reduction techniques, and hardening of magnetometer measurement systems against the effects of earthquake accelerations and displacements. This is apparent in a plot of signal amplitude as a function of time, shown in Figure 1. Post-1960s data are generally considered trustworthy provided care has been taken to ensure sensors are insensitive to seismic shaking and are in regions of low-magnetic-field gradient.

Together with better stability against shaking, an impressive improvement in sensors, sensor reliability, data collection

FIGURE 1 Reported amplitudes of tectonomagnetic anomalies as a function of time. The arrow indicates the time at which absolute proton precession magnetometers and noise reduction techniques were introduced (updated from Rikitake, 1968).

techniques, analysis, and international cooperation has also been apparent during the past few years. Largely as a consequence, reliable observations of magnetic, electric and electromagnetic field variations, related to seismic events and tectonic stress/strain loading, have been obtained on faults in Japan, China, Russia, California, and several other locations.

3. Statement of the Problem

This chapter reviews recent results of magnetic, electric, and electromagnetic disturbances apparently associated with earthquakes and discusses the physical mechanisms likely to have produced them. Although some observations are larger than expected, the best field observations are generally in agreement with calculations. Some observations are suggested as precursors yet have no corresponding co-event signals and some have co-event signals yet no precursory signals. More field observations are clearly needed and more careful work needs to be done to demonstrate convincingly causality, or lack thereof, between EM signals and earthquakes. In particular, further improvement is needed with the use of multiple detectors, use of multiple reference sites, application of noise identification/reduction procedures. Most important is the demonstration of consistency and correlation with other geophysical data that independently reflect the state of stress, strain, material properties, fluid content, and approach to failure of the Earth's crust in seismically active regions.

4. Summary of Physical Mechanisms Involved

The loading and rupture of water-saturated crustal rocks during earthquakes, together with fluid/gas movement, stress redistribution, and change in material properties, has long been expected to generate associated magnetic and electric field perturbations. The detection of related perturbations prior to fault rupture has thus been proposed frequently as a simple and inexpensive method to monitor the state of crustal stress and perhaps to provide tools for predicting crustal failure (Wilson, 1922; Kalashnikov, 1954; Stacey, 1964; Stacey *et al.*, 1965; Yamazaki, 1965; Brace and Orange, 1968a,b; Nagata, 1969; Barsukov, 1972; Rikitake, 1968, 1976; Honkura *et al.*, 1976; Fitterman, 1979, 1981; Ishido and Mizutani, 1981; Varotsos and Alexopoulos, 1987; Dobrovolsky *et al.*, 1989; Sasai, 1980, 1991a,b; Park, 1991; Fujinawa *et al.*, 1992; Fenoglio *et al.*, 1995; Utada, 1993). The primary mechanisms for generation of electric and magnetic fields with crustal deformation and earthquake-related fault failure include piezomagnetism, stress/conductivity, electrokinetic effects, charge generation processes, charge dispersion, magnetohydrodynamic effects, and thermal remagnetization and demagnetization effects.

Discussion of the different mechanisms will be roughly in order of the degree of attention that has been accorded them.

4.1 Piezomagnetism

The magnetic properties of rocks have been shown under laboratory conditions to depend on the state of applied stress (Wilson, 1922; Kalashnikov and Kapitsa, 1952; Kapitsa, 1955; Ohnaka and Kinoshita, 1968; Kean *et al.*, 1976; Revol *et al.*, 1977; Martin, 1980; Pike *et al.*, 1981). Theoretical models have been developed in terms of single domain and pseudo-single domain rotation (Stacey, 1962; Nagata, 1969; Stacey and Johnston, 1972) and multidomain wall translation (Kern, 1961; Kean *et al.*, 1976; Revol *et al.*, 1977). The fractional change in magnetization per unit volume as a function of stress, can be expressed in the form;

$$\Delta \mathbf{I} \approx K \sigma \cdot \mathbf{I} \quad (1)$$

where $\Delta \mathbf{I}$ is the change in magnetization in a body with net magnetization $\mathbf{I}$ due to a deviatoric stress $\sigma \cdot K$, the stress sensitivity, typically has values of about $3 \times 10^{-3} \text{ MPa}^{-1}$. The stress sensitivity of induced and remanent magnetization from theoretical and experimental studies has been combined with stress estimates from dislocation models of fault rupture and elastic pressure loading in active volcanoes to calculate magnetic field changes expected to accompany earthquakes and volcanoes (Stacey, 1964; Stacey *et al.*, 1965; Shamsi and Stacey, 1969; Johnston, 1978; Davis *et al.*, 1979; Sasai, 1980, 1983, 1991a,b; Davis *et al.*, 1984; Johnston *et al.*, 1994; Banks *et al.*, 1991). The surface fields ($\Delta \mathbf{B}_P$) at a point, P , can be calculated in two ways: (1) by either integrating the change in magnetization $\Delta \mathbf{I}_Q$ in a unit volume, dv , at a point Q where the stress is σ_{ij} , and r is the distance between P and Q , according to,

$$\Delta \mathbf{B}_P = -\frac{\mu}{4\pi} \nabla \int_V \Delta \mathbf{I}_Q \cdot \frac{\mathbf{r}}{r^3} dv \quad (2)$$

as originally done by Stacey (1964), or (2) by using a simpler method pioneered by Sasai (1980, 1994) in which analytic expressions of the surface piezomagnetic potential, W , produced by a known stress distribution in a magnetoelastic half-space are obtained by transforming the stress matrix and integrating over the magnetized region. In this latter case, the surface field can be found from:

$$\Delta \mathbf{B}_P = -\nabla W \quad (3)$$

These models show that magnetic anomalies of a few nanoteslas (nT) should be expected to accompany earthquakes for rock magnetizations and stress sensitivities of 1 ampere/meter (A m^{-1}) and 10^{-3} MPa^{-1} , respectively. As shown below, these signals are readily observed with the correct sign and amplitude.

4.2 Stress/Resistivity and Strain/Resistivity effects

In a like manner, the stress dependence of electrical resistivity of rocks has been demonstrated in the laboratory. Resistivity in low porosity crystalline rock increases with compression as a result of crack closure at about 0.2%/bar (Brace *et al.*, 1965) and decreases with shear due to crack opening at about 0.1%/bar (Yamazaki, 1965; Brace and Orange, 1968a,b; Brace, 1975). More porous rocks have even lower stress sensitivity. The situation is further complicated by the fact that non-linear strain can also produce resistivity changes (Lockner and Byerlee, 1986). A stress/resistivity relation equivalent to Eq. (1) has the scalar form

$$\frac{\Delta\rho}{\rho} \approx K_r \sigma \quad (4)$$

for homogeneous material, where ρ is resistivity, K_r is a constant, and σ is the stress. Unfortunately, the earth is not homogeneous and many factors including rock type, crack distribution, degree of saturation, porosity, strain level, etc., can localize or attenuate current flow. Nevertheless, this equation provides a starting point for calculating resistivity changes near active faults. Measurements of resistivity change are being made with both active experiments (where low frequency currents are injected into the ground and potential differences, V , are measured on receiver dipoles), or passive telluric and magnetotelluric (MT) experiments where changes in resistivity are inferred from changes in telluric or MT transfer functions. These transfer functions are given by:

$$Z(\omega) = \frac{E(\omega)}{H(\omega)} \quad (5)$$

where ω is angular frequency, $E(\omega)$ and $H(\omega)$ are observed electric and magnetic fields. For active experiments (Park *et al.*, 1993),

$$\frac{\delta\rho}{\rho} = G \frac{\delta V}{V} \quad (6)$$

where δV is the change in potential difference and G is a constant. For MT experiments,

$$\delta\rho = \frac{\delta|Z(\omega)|^2}{\omega\mu} \quad (7)$$

Based on the field observations of stress changes accompanying earthquakes (≈ 1 MPa), resistivity changes of at least 1% might be expected to accompany crustal failure. Field experiments for detection of resistivity changes thus need to have a measurement precision of better than 0.1% (Fitterman and Madden, 1977; Park, 1991; Park *et al.*, 1993). This may be difficult with MT measurements unless remote magnetic field

reference measurements are used (Gamble *et al.*, 1979) although measurement precision for telluric electric fields can be made at the 0.1% level (Madden *et al.*, 1993).

4.3 Electrokinetic Effects

The role of active fluid flow in the Earth's crust as a result of fault failure can generate electric and magnetic fields (Mizutani and Ishido, 1976; Fitterman, 1978, 1979; Ishido and Mizutani, 1981; Dobrovolsky *et al.*, 1989; Fenoglio *et al.*, 1995). Electrokinetic electric and magnetic fields result from fluid flow through the crust in the presence of an electric double layer at the solid-liquid interfaces. This double layer consists of ions anchored to the solid phase, with equivalent ionic charge of opposite sign distributed in the liquid phase near the interface. Fluid flow in this system transports the ions in the fluid in the direction of flow, and electric currents result. Conservation of mass arguments (Fenoglio *et al.*, 1995) supported by surface strain observations (Johnston *et al.*, 1987) limit this process in extent and time because large-scale fluid flow cannot continue for very long before generating easily detectable surface deformation.

The current density $\mathbf{j}$ and fluid flow $\mathbf{v}$ are found from coupled equations (Nourbehecht, 1963; Fitterman, 1979) given by

$$\mathbf{j} = -s\nabla E - \frac{\xi\zeta\nabla P}{\eta} \quad (8)$$

$$\mathbf{v} = \frac{\phi\xi\zeta\nabla E}{\eta} - \frac{\kappa\nabla P}{\eta} \quad (9)$$

where E is streaming potential, s is the electrical conductivity of the fluid, ξ is the dielectric constant of water, η is fluid viscosity, ζ is the zeta potential, ϕ is the porosity, κ is the permeability, and P is pore pressure.

The current density in Eq. (8) has two components. The second term represents electric current resulting from mechanical energy being applied to the system and is sometimes called the “impressed” current (Williamson and Kaufman, 1981). This term describes current generated by fluid flow in fractures. The first term of Eq. (8) represents “back” currents resulting from the electric field generated by fluid flow. The distribution of electrical conductivity determines the net far-field magnetic and electric fields resulting from these effects. In an extreme case, if the fluid is extremely conducting and the surrounding region is not, current flow in the fluid cancels the potential generated by fluid flow (Ahmad, 1964). At the other extreme, if the fluid is poorly conducting, “back” currents, usually termed “volume currents” (Williamson and Kaufman, 1981) flow in the surrounding region. If the region were homogeneous, magnetic fields would be generated by impressed currents only since the volume currents generate no net field (Fitterman, 1979; Fenoglio *et al.*, 1995). The situation for finite flow in limited fault fractures more closely

approximates the second case where the surface magnetic field is approximately given by:

$$\mathbf{B} = \frac{\mu_0}{4\pi} \int_A \frac{\mathbf{j}_i \times \mathbf{r}}{r^2} dA \quad (10)$$

where μ_0 is the magnetic permeability in free space. Note that, the physics describing the electric and magnetic fields generated in the human body as blood is pumped through in arteries provides a very good analog to those generated in fault zones (Williamson and Kaufman, 1981). This occurs because the electrical conductivities of bone (0.001 S m^{-1}), muscle (0.1 S m^{-1}) and blood (1 S m^{-1}) and blood velocities are similar to those of rock, fault gouge, fault zone fluids, and the likely fluid velocities determined by Darcy Law fluid diffusion in fault zones. Considerable work has been done in understanding the physics of electric and magnetic field generation in the human body and this can be applied directly to crustal faulting situations. Reasonable fault models, in which fluid flows into a 200 m long rupturing fracture at a depth of 17 km, indicate that transient surface electric fields of several tens of millivolts per kilometer and transient magnetic fields of a few nT can be generated (Fenoglio *et al.*, 1995).

4.4 Charge Generation Processes

Numerous charge generation mechanisms have been suggested as potential current sources for electric and magnetic fields before and during earthquakes. These mechanisms include piezoelectric effects (Finkelstein *et al.*, 1973; Baird and Kennan, 1985), triboelectricity effects produced by rock shearing (Lowell and Rose-Innes, 1980; Gokhberg *et al.*, 1982; Brady, 1992), fluid disruption/vaporization (Blanchard, 1964; Matteson, 1971; Chalmers, 1976), and solid state mechanisms (Dologlou-Revelioti and Varotsos, 1986; Freund *et al.*, 1992). Each of these mechanisms has a solid physical basis supported by laboratory experiments on either dry rocks in insulating environments or single crystals of dry quartz. Each is capable of producing substantial charge under the right conditions. However, at least two fundamental problems need to be studied in the application of charge-generation processes to EM field generation in the Earth's crust. The first concerns the amplitude of each charge generation effect in wet rocks at temperatures and pressures expected in the Earth's crust and the second concerns charge maintenance time and propagation in the conducting crust.

Regarding the first problem, experiments clearly need to be done for each mechanism to quantify the effects expected in wet rocks at temperatures of at least 100°C and at confining pressures of 100 MPa expected at earthquake hypocenters. Experiments on dry rocks at atmospheric pressure are not very relevant to this issue. Piezoelectric effects in dry quartz bearing rocks are less than 0.1% of those observed for single crystals of quartz due to self canceling effects (Tuck *et al.*,

1977; Sasaoka *et al.*, 1998), and effects in wet rocks will likely be smaller still and transient at best. EM generation by fracturing dry rocks (Warwick *et al.*, 1982; Brady, 1992) needs to be extended to wet rocks under confining pressure. Experiments on hole transport of O_2 in dry rocks (Freund *et al.*, 1992) and stress charging of dry nonpiezoelectric rocks (Dologlou-Revelioti and Varotsos, 1986) need also to be repeated with wet rocks under confining pressure so that these effects can be quantified. Brady (1992) observed no EM emission during fracture of conductive rocks since the conductor could not maintain charge separation.

The second fundamental problem concerns the discharge time for these processes and just how far EM signals generated by them might propagate. The charge relaxation time τ for electrostatic processes is given by the product of permittivity (ϵ) and resistivity (ρ). ϵ is $0.5\text{--}1.0 \times 10^{-10} \text{ F m}^{-1}$ for crustal rocks. If $\rho \approx 10^3 \text{ ohm.m}$ (typical upper value for near fault crustal rock) then,

$$\tau \approx 10^{-6} \text{ sec} \quad (11)$$

Although polarization effects (Lockner and Byerlee, 1985) will generate somewhat longer timescales (perhaps as much as a second), EM signal generation by charge generation processes must necessarily still be very rapid unless mechanisms can be found for isolating and maintaining large charge densities in a conducting earth. Furthermore, dispersion precludes EM fields propagating very far in a conducting earth (Honkura and Kuwata, 1993).

Attenuation of the magnetic field, B , of a plane electromagnetic wave generated at depth by charge generation/cancellation processes as a function of penetration distance through a conductive medium is given by:

$$B = B_0 e^{-\gamma z} \quad (12)$$

where B_0 is the initial field strength, z is the penetration distance into the medium, and γ is the complex propagation coefficient given by:

$$\gamma = \sqrt{\omega^2 \mu \epsilon + j \omega \mu s} \quad (13)$$

where ω is the angular frequency of the radiation, μ is the magnetic permeability of the earth, ϵ is the permittivity, and s is the conductivity of the medium. If s is 0.1 S m^{-1} , the frequency is 0.01 Hz, the "skin depth" is 10 km, so fields generated at this depth could be observable at the earth's surface.

If these fields are generated by rock cracking and fracturing, acoustic (seismic) signals should also be generated (see Lockner *et al.*, 1991). Seismic wave attenuation with distance z has the form

$$A(z) = A_0 \exp^{-(\omega z/2cQ)} \quad (14)$$

where ω is the angular frequency, c is the phase velocity, and Q is the quality factor. Taking observed values of 3 km sec^{-1} and 30 for c and Q , it can easily be shown that seismic waves in the frequency band 1–0.01 Hz are not attenuated significantly in the epicentral area. At higher frequencies, both seismic and EM signals are heavily attenuated. For example, at 10 Hz the EM “skin depth” is 493 m in material with conductivity of 0.1 S m^{-1} and the seismic equivalent “penetration depth” is 2864 m. At 100 Hz the comparative depths are 156 m, 286 m, and at 1 KHz 29 m, 49 m, respectively.

Thus, both high frequency seismic and EM waves are heavily attenuated in the earth’s crust. EM sources at 10 Hz should have an acoustic component that is more easily detected over a greater area. In fact, for all EM sources at seismogenic depths capable of propagating to the earth’s surface (i.e., with frequencies less than 0.1 Hz), acoustic/seismic consequences of these sources propagate more effectively to the surface and might be used to verify their existence.

4.5 Magnetohydrodynamic (MHD) Effects

The induced magnetic field $\mathbf{B}_i$ generated by the motion $\mathbf{v}$ of a fluid with conductivity s in a magnetic field $\mathbf{B}_0$, is governed by the equation:

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times \mathbf{v} \times \mathbf{B} + \frac{\nabla^2 \mathbf{B}}{\mu_0 s} + \frac{\nabla s \times \nabla \times \mathbf{B}}{\mu_0 s^2} \quad (15)$$

where μ_0 is the permeability in a vacuum (Shercliff, 1965). For low magnetic fields and low electrical conductivities in the Earth’s crust where the fluid motion is not affected by the induced fields, the induced field is given approximately by the product of the magnetic Reynolds number R_m and the imposed field $\mathbf{B}_0$, i.e.,

$$\mathbf{B}_i \approx R_m \times \mathbf{B}_0 \approx \mu s \mathbf{v} d \mathbf{B}_0 \quad (16)$$

where d is the length scale of the flow. Critical parameters here are the likely flow velocities and fluid electrical conductivities in the crust. Flow velocity is determined by rock permeability and fluid pressure gradients according to Darcy’s Law. Permeability of fractured rock is not less than 10^{-12} m^2 (Brace, 1980) and pore-pressure gradients cannot exceed the lithospheric gradient. It is difficult to achieve widespread flow velocities of even a few millimeters sec^{-1} with this mechanism. Furthermore, fluid conductivities are unlikely to exceed that of sea water ($\approx 1 \text{ S m}^{-1}$). Using these numbers, fluid flow in fractured fault zones at seismogenic depths ($\approx 5 \text{ km}$) with a length scale of 1 km could generate transient fields of about 0.01 nT. This is far too small to be observed at the Earth’s surface. As a check on these calculations, we note that fields of a few nT are observed with waves in the ocean where the conductivity is 1 S m^{-1} and wave velocities exceed 100 cm sec^{-1} (Fraser, 1966).

4.6 Thermal Remagnetization and Demagnetization

Crustal rocks lose their magnetization when temperatures exceed the Curie Point ($\approx 580^\circ\text{C}$ for magnetite) and become remagnetized again as the temperature drops below this value. Stacey and Banerjee (1974) describe this process in detail. In crustal rocks at seismogenic depths near active faults, this process is unlikely to contribute to rapid changes in local magnetic fields since the thermal diffusivity of rock is typically about $10^{-6} \text{ m}^2 \text{ sec}^{-1}$ and migration of the Curie Point isotherm by conduction cannot be as much as a meter in a year (Stacey, 1992). At shallow depths in volcanic regions, particularly in recently emplaced extrusions and intrusions, thermal cracking with gas and fluid movement can transport heat rapidly and large local anomalies can be quickly generated (Rikitake and Yokoyama, 1955; Hurst and Christoffel, 1973; Emeleus, 1977; Zlotnicki and Le Mouel, 1988; Hamano *et al.*, 1990; Dzurisin *et al.*, 1990; Zlotnicki and Le Mouel, 1990; Tanaka, 1993, 1995). These anomalies can be modeled as a magnetized slab in a half-space. Good examples of magnetic modeling of anomalies generated by cooling of extrusions can be found in Dzurisin *et al.* (1990) for Mt. St. Helens and in Tanaka (1995) for Mt. Unzen in Japan. Some seasonal variations may result from annual temperature diffusion into magnetic rocks in the upper few meters of the Earth’s crust (Utada *et al.*, 2000).

5. Experimental Design and Measurement Precision

5.1 Basic Measurement Limitations

The precision of local magnetic and electric field measurements on active faults varies as a function of frequency, spatial scale, instrument type, and site location. Most measurement systems on the Earth’s surface are limited more by noise generated by ionosphere, magnetosphere, and by cultural noise than by instrumental noise. Thus, systems for quantifying these noise sources are of crucial importance if changes in electromagnetic fields are to be uniquely identified. For spatial scales of a few kilometers to an few tens of kilometers, comparable to moderate magnitude earthquake sources, geomagnetic and electric noise power decreases with frequency as $1/f^2$, similar to the “red” spectrum behavior of most geophysical parameters (Johnston *et al.*, 1984). Figure 2 shows an example of a noise power spectrum for two typical sites 10 km apart on the San Andreas fault in regions of low local magnetic gradient and far from sources of cultural noise (after Ware *et al.*, 1985).

Against this background noise, transient magnetic fields can be measured to several nanotesla over months, to 1 nT over days, to 0.1 nT over minutes, and 0.01 nT over seconds. Long-term changes and field offsets can be determined if their amplitudes exceed about 1 nT. Comparable electric field noise

FIGURE 2 Power spectral density of simultaneous differences between sites 10 km apart on the San Andreas fault near San Juan Bautista. The self-calibrating rubidium (SCR) data are consecutive 10 sec measurements with a 0.014 nT least count. The 0.125 least-count proton magnetometer (PM) data are 1.5 sec averages taken every 15 sec (after Ware *et al.*, 1985).

limits are 10 mV km^{-1} over months, several mV km^{-1} over days, 1 mV km^{-1} over minutes and 0.1 mV km^{-1} over seconds (derived from Park, 1991). EM noise increases approximately linearly with site separation (Johnston *et al.*, 1984). Cultural noise further complicates measurement capability because of its inherent unpredictability. This largely precludes measurements in urban areas.

5.2 Experimental Techniques

Thus, unambiguous observations of EM signals originating within the Earth's crust require well-planned experiments to discriminate against these ionospheric, magnetospheric, and cultural noise sources. At lower frequencies (microhertz to hertz) for both electric and magnetic field measurements, the most common technique involves the use of reference sites with synchronized data sampling in arrays using site spacing comparable to the expected source sizes of a few kilometers (Rikitake, 1966; Johnston *et al.*, 1984; Park and Fitterman, 1990; Park 1991; Varotsos and Lazaridou, 1991). This relatively simple system allows as much as a 30 dB reduction in noise (Park, 1991; Johnston *et al.*, 1984). Techniques for further noise reduction such as adaptive filtering (Davis *et al.*, 1981; Davis and Johnston, 1983), use of multiple variable-length sensors in the same and nearby locations (Varotsos and Alexopoulos, 1987; Mori *et al.*, 1993), provide about a factor of three further improvement.

Although these same techniques can be applied to electromagnetic field measurements at higher frequencies (100 Hz to MHz) much less is known about the scale and temporal

variation of noise and signal sources at these frequencies. Furthermore, as discussed below, basis physics likely precludes simple generation of high-frequency electromagnetic signals at seismogenic depths (5–10 km) on active faults in the Earth's crust where the electrical conductivity is more than 0.1 S m^{-1} .

6. Recent Results

Although both electric and magnetic fields are expected to accompany dynamic physical processes in the Earth's crust, simultaneous measurements of both fields are not routinely made. I will therefore discuss separately, electric fields, magnetic fields, and electromagnetic fields during and preceding earthquakes. Magnetic and electric fields generated by earthquakes are termed "seismomagnetic (SM)" and "seismo-electric (SE)" effects. Those preceding earthquakes, or occurring at other times, are termed "tectonomagnetic (TM)" and "tectonoelectric (TE)" effects.

If reliable magnetic and electric field observations (i.e., those unaffected by seismic shaking) are indeed source related, clear offsets should occur at the time of large local earthquakes because the primary energy release occurs at this time. These offsets should scale with the earthquake moment (size) and source geometry. In fact, co-event observations provide a determination of stress sensitivity since the stress redistribution and the source geometry of earthquakes are well-determined (Aki and Richards, 1980). With this calibration, tectonomagnetic and tectonoelectric effects can be quantified and spurious effects identified. Observations without consistent and physically sensible coseismic effects are generally considered suspect.

The following examples are restricted to the strongest data: data recorded independently on more than one instrument, data that are independently supported by other stable geophysical measurement systems, and data for which noise levels have been quantified. Reported measurements made with single instruments or time histories of measurements showing data only for a short period before earthquakes with some "pre-cursive" feature but no coseismic signals, are generally suspect and are not included.

6.1 Seismomagnetic Effects

The primary features of seismomagnetic effects have become clear over the past twenty years with many continuous high-resolution magnetic field measurements in the epicentral regions of moderate-to-large earthquakes. Figure 3 shows a summary of observed SM effects as a function of earthquake moment normalized by epicentral distance. The following features are immediately apparent on this plot:

1. SM effects are observed above the measurement resolution in the near field of earthquakes only when the earthquake magnitude is $M = 6$ or greater.

FIGURE 3 Coseismic magnetic field offsets as a function of seismic moment scaled by hypocentral distance. The region below the horizontal line shows the 2-sigma measurement resolution (from Mueller and Johnston, 1998).

2. The amplitudes of SM effects within one rupture length of these earthquakes are not more than 1 nT or so.

Coseismic strain measurements at these same locations for some of these earthquakes are a few microstrain (Johnston *et al.*, 1987). Thus, a good rule of thumb for estimating the expected SM effects, where strain observations are available, is to use a scaling factor of 1 nT per microstrain. A similar scaling factor was obtained from correlation between geodetic strain and local geomagnetic fields during aseismic deformation, uplift, and gravity changes in Southern California in the 1980s (Johnston, 1986).

6.1.1 *M* = 7.3 Landers Earthquake (28 June 1992)

An important set of observations of SM effects were made during the 28 July 1992 Landers earthquake (Johnston *et al.*, 1994). This earthquake had a moment of 1.1×10^{27} dyne cm and a magnitude of 7.3. Two total field proton magnetometers were in operation at distances of 17.1 and 24.2 km from the earthquake and have recorded synchronously sampled local magnetic fields every 10 min since early 1979 using satellite digital telemetry (Mueller *et al.*, 1981). The locations are shown in Figure 4.

The local magnetic field at the magnetometer closest to the earthquake decreased by 1.2 nT while that at the second decreased by 0.7 nT. These values are consistent with a simple SM model of the earthquake in which the fault geometry and slip used are derived from geodetic and seismic inversions of the earthquake data (Johnston *et al.*, 1994). Figure 5a shows the differences between data obtained at the two sites OCHM and LSBM for the period 1 day before and after the earthquake. Note that there is no indication of diffusion-like

character in the magnetic field offsets that might indicate these effects were generated by fluid flow, nor are there any indications of enhanced low-frequency magnetic noise preceding the earthquake or indications of changing magnetic fields outside the noise in the hours to days before the earthquake. Figure 5b shows the longer-term data for the previous 7 y. The SM effect from the 1986 *M* 6 North Palm Springs earthquake which occurred beneath these same two instruments is clearly evident (Johnston and Mueller, 1987). Similar coseismic results were found for the 1989 *M* 7.1 Loma Prieta earthquake (Mueller and Johnston, 1990).

6.2 Seismoelectric Effects

Seismoelectric observations that show expected scaling with both earthquake moment release and inverse distance cubed are difficult to make because of the sensitivity of electrode contact potential to earthquake shaking. Earlier work by Yamazaki (1974) showed clear correspondence between local coseismic strain steps and coseismic resistivity steps obtained using a Wenner array with a measurement precision of 0.01%. Strain measurements obtained with deep borehole strainmeters (Johnston *et al.*, 1987) or with geodetic techniques (e.g., Lisowski *et al.*, 1990) do reflect the strain/stress expected from seismically determined models of earthquakes. SE effects should be expected to do likewise. Unfortunately, the effects of shaking on contact potential and on self-potential, as a result of changes in fluid content and fluid chemistry, make these data unreliable reflectors of earthquake stress changes (Ozima *et al.*, 1989). Clearly, colocated strain measurements (at tidal sensitivity) and electric field measurements are needed to demonstrate the sensitivity of the electric field measurements to changes in stress/strain in the Earth's crust. This, and observations on multiple sensors with stable electrodes (Petiau and Dupis, 1980; Perrier *et al.*, 1997) are necessary to have real confidence in SE measurements as earthquake monitors and perhaps as precursor detectors.

Measurements of electrical resistivity to better than 1% have been made since 1988 in a well-designed experiment installed near Parkfield, California (Park, 1997). Although the expected *M* = 6 earthquake in this region has not occurred, several earthquakes with *M* = 5 have occurred since 1990. None of these earthquakes generated any observable changes in resistivity above the measurement resolution. Observations for three of these dipoles during the times of these earthquakes, and other larger but more distant earthquakes, are shown in Figure 6.

Indirect observations of possible SE signals might be obtained using the magnetotelluric (MT) technique to monitor apparent resistivity in seismically active regions. Even with the best-designed systems using remote referencing systems to reduce noise and obtain stable impedance tensors (Gamble *et al.*, 1979), it is difficult to reduce errors below 5% for good soundings and 10–40% for poor soundings (Ernst *et al.*, 1993).

FIGURE 4 Locations of magnetometers, designated LSBM and OCHM (stars inside circles) relative to the epicenter (largest star) of the 28 June 1992 $M = 7.3$ Landers earthquake (from Johnston *et al.*, 1994).

Resistivity changes associated with earthquakes are expected (and are observed) to be only a few percent at best. Thus, it is unlikely that this technique will be used generally for detection of resistivity changes. The pioneering work of Honkura *et al.* (1976) still largely defines the limits of observability for MT observations, though some interesting ways of using MT to detect EM emissions with earthquakes have been explored by Rozluski and Yukutake (1993).

6.3 Tectonomagnetic and Possible Precursory Effects

Few indications of convincing longer-term tectonomagnetic events (i.e., durations greater than minutes to weeks) are apparent in multiple near-field magnetometer records obtained along active faults as a result of strain redistribution prior to

moderate/large earthquakes. Only one such observation was made in 20 years of data along the San Andreas fault (Mueller and Johnston, 1998). A typical record of long-term magnetic field near active faults is shown in Figure 5b. Signals of more than a few nanoteslas are rare and are of great interest when they occur. If signal amplitudes near active faults are only about a nanotesla, it is unlikely that any reported precursive signals at great epicentral distances are truly earthquake related. Long-term relatively uniform changes, apparently related to crustal loading have been previously reported (Johnston, 1989; Oshiman *et al.*, 1983).

The situation may be different at higher frequencies (i.e., ≥ 0.01 Hz). Recent efforts have been concentrated at these higher ultralow frequency (ULF) frequencies as a result, primarily, of fortuitous observation of elevated ULF noise power near the epicenter of the $M = 7.1$ Loma Prieta earthquake of

FIGURE 5 (a) Magnetic field differences between OCHM and LSBM (for location see Fig. 4) on the day before and after the Landers earthquake. (b) Similar magnetic field differences from 1985 through 1992 showing the occurrence times of the July 1986 $M=6$ North Palm Springs earthquake and the June 1992 Landers earthquake (from Johnston *et al.*, 1994).

18 October 1989 (Fraser-Smith *et al.*, 1990). The magnetometer was located only 7 km from the epicenter (Fig. 7) and recorded increased ULF noise reaching 1.5 nT in amplitude during the two weeks before, and a few hours before the earthquake (Fig. 8). A second system recording ULF/VLF (very low frequency) data 52 km from the earthquake showed

no corresponding changes. Similar records were not obtained during the $M=6.7$ Northridge earthquake at a distance of 81 km from the epicenter (Fraser-Smith *et al.*, 1994), for the $M=7.3$ Landers earthquake, or on magnetic and electric field instruments at the epicenter of the 17 August 1999 $M=7.4$ Izmet earthquake in Turkey (Honkura *et al.*, 2000).

Table 1 Significant Parkfield and California Earthquakes

Event	Date	Latitude (°N)	Longitude (°N)	M_b	Depth (km)	Distance (km)
A	Oct. 20, 1992	35.93	120.47	4.5	10.0	6.1
B	Apr. 4, 1993	35.94	120.49	4.3	7.6	8.5
C	Nov. 14, 1993	35.95	120.50	4.0	11.6	9.5
D	Dec. 20, 1994	35.92	120.47	5.0	8.6	4.7
E	Oct. 18, 1989	37.04	121.88	7.0	---	180.0
F	Jun. 28, 1992	34.20	116.43	7.2	---	410.0
G	Jan. 17, 1994	34.19	118.57	6.6	---	250.0
H	May 25, 1989	35.87	120.41	3.6	9.6	3.3

E, Loma Prieta; F, Landers; G Northridge. Distance is measured from array center.

FIGURE 6 Plots of telluric fields at Parkfield, Ca., from 1988 to 1996. Earthquakes A–H (listed in the Table) have occurrence times shown with arrows (from Park, 1997).

Although the Loma Prieta record was recorded on only one magnetometer and therefore violates the multiple instrument requirement discussed above, the instrument was surrounded by independent seismic and strain instrumentation and the data were uncontaminated by cultural noise. For these reasons this example is included here.

For the Loma Prieta observations, Fenoglio *et al.* (1993) have shown that there is no correlation between the ULF anomalies and either the magnitudes or the rates of aftershocks. The absence of signals for these smaller magnitude earthquakes, or for larger earthquakes at greater distances, indicates a localized source for these oscillatory signals. Draganov *et al.* (1991) have suggested a magnetohydrodynamic origin, whereas Fenoglio *et al.* (1995) have suggested an electrokinetic source generated by fluid flow following rupture of high-pressure fluid-filled inclusions in the fault zone.

FIGURE 7 Location of ULF receiver at Corralitos, 7 km from the epicenter of the 18 Oct. 1989 $M=7.1$ Loma Prieta earthquake. A second receiver was located at Stanford University (from Fraser-Smith *et al.*, 1990).

FIGURE 8 Magnetic field amplitude as a function of time during the 17 days before and 14 days after the Loma Prieta earthquake at 00:04 on 17 Oct. 1989 (from Fraser-Smith *et al.*, 1990).

6.4 Tectonoelectric and Possible Precursory Effects

The clearest tectonoelectric changes resulting from changes in crustal resistivity were reported in the Tangshan region of China prior to the 1976 Haicheng earthquake (Qian, 1981).

Other interesting, though unexplained changes occurred in the Palmdale region of the San Andreas fault (Madden *et al.*, 1993) following the infamous “Palmdale Bulge”. These changes occurred in the same region where correlated tectonometric, gravity, strain, and elevations had been reported earlier (Johnston, 1986).

Increased, though controversial, interest in tectonoelectric (TE) phenomena related to earthquakes has occurred during the past ten years, primarily as a result of suggestions in Greece and Japan that short-term geoelectric field transients (SES) of particular form and character precede earthquakes with magnitudes greater than 5 at distances up to several hundreds of kilometers (Varotsos *et al.*, 1993a,b; Nagao *et al.*, 1996). These transients are recorded on multiple dipoles with different lengths (10–200 m for short arrays and 1–3 km for longer ones) with signal amplitudes of 20 mV km^{-1} and durations of several minutes. The observation of consistent electric field amplitudes independent of dipole length indicates a local spatially uniform source field. However, there are no corresponding magnetic field transients and no apparent coseismic effects. The SES have been empirically associated

with subsequent distant earthquakes in “sensitive” areas (Varotsos *et al.*, 1991, 1993a,b, 1996). An example of an SES recorded on multiple orthogonal dipoles together with parallel recordings of magnetic field rate at Ioannina in northwest Greece on 18 April 1995, is shown in Figure 9. This SES was suggested to have preceded a $M=6.6$ earthquake on 13 May 1995, some 83 km to the northeast. Two other large earthquakes, the $M=6.6$ on 4 May at Chalkidiki and the 15 June $M=6.5$ Eratini earthquake, were also suggested to have been predicted by SES on distant stations several weeks before. Similar experiments have been run in Japan, France, and Italy with various levels of claimed success. Nagao *et al.* (1996) suggest that anomalous SES may have been recorded prior to the $M=7.8$ Hokkaido earthquake in June 1993.

Careful study of the SES recordings indicates that the SES signals do appear to have been generated in the Earth’s crust at the observation sites (Uyeshima *et al.*, 1998). However, the SES signals have the form expected from rectification/saturation effects of local radio transmissions from high-power transmitters on nearby military bases (Pham *et al.*, 1998). Also, no clear physical explanation exists describing how the

FIGURE 9 Observed SES recorded on multiple dipoles on 19 April 1995 at the Ioannina Station. Simultaneous measurements of magnetic field gradient are shown in the lower two plots (from Varotsos *et al.*, 1996).

SES signals can relate to earthquakes occurring sometimes hundreds of kilometers away (Bernard, 1992) whereas sites closer to the earthquake do not record SESs and do not have coseismic effects corresponding to the primary earthquake energy release. Without a clear causal relation, demonstration of statistical significance is controversial (Mulargia and Gasperini, 1992; Hamada, 1993; Shnirman *et al.*, 1993; Aceves *et al.*, 1996; Varotsos *et al.*, 1996; Debate on VAN, 1996; Lighthill, 1996). Better physical understanding is certainly needed. This could be obtained by careful monitoring of the nearby radio transmissions and study of the response of these transmissions on the measuring systems and on the electrical conductivity structure around sites where SESs are recorded. Independent information on the other local sources can be obtained from measurements of high-precision crustal strain, fluid levels in wells, and local pore pressure. The absence of correlative signals in these parameters would further support Pham *et al.*'s (1998) suggestions that these SESs are spuriously generated by local radio transmissions.

6.5 Electromagnetic Effects

Another enigma concerns the generation of high frequency (≥ 1 kHz) electromagnetic emissions prior to moderate earthquakes. Such emissions are reported to have been detected at great distances from these earthquakes (Gokhberg *et al.*, 1982; Oike and Ogawa, 1986; Yoshino *et al.*, 1985; Yoshino, 1991; Parrot *et al.*, 1993; Fujinawa and Takahashi, 1994; Hayakawa and Fujinawa, 1994; Shalimov and Gokhberg, 1998; Kawate *et al.*, 1998; Ondoh, 1998) and are also reported to have been detected in satellite data (Molchanov *et al.*, 1993; Parrot, 1994), although the statistical significance of these observations is under dispute (Henderson *et al.*, 1993; Molchanov *et al.*, 1993; Parrot, 1994). This area of research has received attention following reports of changes in the level of 81-kHz electromagnetic radiation around the time of a $M = 6.1$ earthquake at a depth of 81 km beneath the receiver (Gokhberg *et al.*, 1982). Radio emissions at 18 MHz were recorded at widely separated receivers in the northern hemisphere for about 15 min before the 16 May 1960 great Chilean $M_w = 9.5$ earthquake (Warwick *et al.*, 1982).

Although generation of high frequency electromagnetic radiation can be easily demonstrated in controlled laboratory experiments involving rock fracture in dry rocks (Warwick *et al.*, 1982; Brady and Rowell, 1986; Brady, 1992), the physical mechanisms for the generation and the method of propagation of very high frequency (VHF) electromagnetic waves through many tens to hundreds of kilometers of conducting crust (and through the ocean) are not at all clear. Furthermore, the absence of significant local crustal deformation in the epicentral regions of earthquakes during the months to minutes before rupture would seem to strongly constrain the scale of precursive failure. These strain data show that precursive moment release is less than 1% of that

occurring coseismically (Johnston *et al.*, 1987). As discussed above, simple "skin depth" attenuation arguments preclude sources generating fields, in the kilohertz to megahertz range tens to hundreds of kilometers deep in a conducting crust ($1-0.001 \text{ S m}^{-1}$), that would be detectable at the Earth's surface. Appeal to secondary sources at the Earth's surface (Yoshino and Sato, 1993) may avoid this difficulty but the implied large surface strain and displacement fields are not observed.

High frequency disturbances are, of course, generated in the ionosphere as a result of coupled infrasonic waves generated by earthquakes and are readily detected with routine ionospheric monitoring techniques and Global Position System (GPS) measurements (Calais and Minster, 1998). Essentially, the displacement of the Earth's surface by an earthquake acts like a huge piston, generating propagating waves in the atmosphere/ionosphere waveguide (Davies and Archambeau, 1998; see review of gravity waves in the atmosphere by Francis, 1975). Thus, traveling waves in the ionosphere (traveling ionospheric disturbances or TIDs) are a consequence of earthquakes (and volcanic eruptions). EM data at VHF frequencies recorded on ground receivers or by satellite require correction for TID disturbances (and disturbances from other sources) before these data can be identified as direct electromagnetic precursors to earthquakes, or consequences of earthquakes.

7. Conclusions

In summary, improved measurements of magnetic, electric, and electromagnetic fields being made in the epicentral regions of earthquakes around the world, have led to the recognition that observed field perturbations are generated by a variety of EM source processes. It is also clear there are many problems that still need to be resolved. In particular, a clearer understanding of physical processes involved will result from systematic work on:

1. Inclusion of constraints on the various physical mechanisms and models of various processes that are imposed by data from other disciplines such as seismology, geodesy, etc.
2. Demonstration of self-consistency in observations;
3. Determination and inclusion of realistic signal-to-noise estimates.
4. Identification of local noise sources.
5. Checking the implications of these data in other geophysical data obtained in the area. Unusual records can no longer be claimed as precursors just because they precede, or correspond approximately in time, to some local or distant earthquakes. They must be consistent with high-precision seismic and deformation data simultaneously obtained in the near field of each of the earthquakes.

6. Use of reference stations to quantify and remove common-mode noise generated in the ionosphere/magnetosphere.
7. Isolation of the most likely location of signal sources in the Earth's crust consistent with all available data. This appears to be particularly neglected in recent associations of ULF/VLF data with earthquakes.

On the positive side, better understanding has been obtained from well-designed experiments with multiple independent instrument types recording in the same frequency band. This has allowed quantification of at least some of the mechanisms generating electromagnetic fields with tectonic and volcanic activity. It now seems likely that:

1. Stress-generated magnetic effects (piezomagnetic effects) are readily observed as a result of crustal stress drops for earthquakes with $M \geq 6$ such as during the $M=7.1$ Loma Prieta earthquake on the San Andreas fault in 1989, the $M=7.3$ Landers earthquake in 1992 and the $M=6$ North Palm Springs earthquake in 1986.
2. Precursive EM fields are rare in both low frequency and high frequency electromagnetic field data above the measurement resolution of 0.01 nT at 100 Hz to a few nT at hours to days for local magnetic fields and 0.01 mv km^{-1} at 100 Hz to 1 mv km^{-1} at hours to days for electric fields.
3. Electrokinetic effects probably occurred during the $M=7.1$ Loma Prieta earthquake in 1989.

Finally, it is obvious that more complete observational arrays are needed in critical locations to provide a sound database for EM studies. Earthquakes occur infrequently and great skill is needed to "catch" these events with adequate arrays so we can better understand the physical processes involved.

Acknowledgments

I would like to thank Steve Park, Tony Fraser-Smith, Bob Mueller and other colleagues for stimulating discussions. Larry Byer and Yoshimori Honkura provided useful reviews.

Earthquake-related Hydrologic and Geochemical Changes

Chi-Yu King

Earthquake Prediction Research, Inc., Los Altos, USA

George Igarashi

The University of Tokyo, Tokyo, Japan

1. Introduction

The “solid” earth contains abundant fluids that have been continuously released and partly recycled through geological time. The outgassing process is generally believed to be responsible for the origin of the atmosphere and hydrosphere. The rate of outgassing evidently has not been uniform in either time or space over the Earth’s surface but depends on the chemical composition, the physical condition, the geological structure, and the movement of materials in the ground. A considerable amount of study on various terrestrial fluids has been carried out in recent years by scientists working in a wide variety of fields of investigation, including the origin and evolution of the atmosphere and hydrosphere, the Earth’s interior, plate tectonics, the mechanism and prediction of earthquakes and volcanic eruptions, the exploration of buried oil, gas, and mineral resources, the disposal of nuclear waste, and the environmental impact of terrestrial gas emissions such as indoor radon pollution (e.g., Ozima and Podosek, 1983; Parnell, 1994, 1998; Metcalfe and Rochelle, 1999). Several collective publications of multidisciplinary studies on subsurface fluid flow in and near fault zones have been published (e.g., Hickman *et al.*, 1995; Jones *et al.*, 1998; McCaffrey *et al.*, 1999; Haneberg *et al.*, 1999).

In this chapter we provide a brief review of studies on hydrologic and geochemical changes observed before, at the time of, and after earthquakes (other than seismic oscillations) during the past several decades. Such studies were usually conducted for the purpose of better understanding the mechanics of earthquakes and the possibility of earthquake prediction, as many geophysical studies. The study of hydrologic and geochemical changes may provide clues for understanding some other earthquake-related phenomena, such as electromagnetic changes (see Chapter 38 by Johnston) and abnormal animal behavior. Earthquake

prediction is probably the most challenging problem in earth science today; its feasibility has long been under debate (e.g., Geller, 1997). Crustal fluids may play an active role in generating earthquakes and nonseismic fault movement, but this kind of study is not reviewed here (see Chapter 40 by McGarr *et al.*).

2. Earlier Observations

Hydrologic and geochemical changes, such as anomalous water-level/color changes and occurrence of strange odors, at about the time of earthquakes have been observed since ancient times in many seismic regions. A systematic search for earthquake precursors for the purpose of earthquake prediction with scientific instruments did not begin, however, until the 1960s. Earlier results of such studies, conducted mainly in China, Japan, the former Soviet Union, and the United States, were reviewed by King (1986), Thomas (1988), Ma *et al.* (1990), Igarashi and Wakita (1995), and Roeloffs (1988, 1996), among others. In this section we provide only a brief summary of the general features of the observations obtained before mid-1980s.

Hydrologic and geochemical parameters investigated include water level/pressure, temperature, and electric conductivity at wells, flow rate at springs, concentration of various ions and dissolved gases, and components of soil gas in shallow holes. Earthquake-related changes were reportedly observed beginning hours to years before many destructive earthquakes mainly at certain “sensitive” monitoring sites, among many insensitive sites. The sensitive sites were usually found to be located along active faults, especially at intersections of faults, and may be at unexpectedly large epicentral distances (many source dimensions, or hundreds of kilometers for large events). The long-distance changes were difficult to understand on the basis of dislocation models of earthquake

sources in a homogeneous and elastic medium. Because of this difficulty and because of the existence of many insensitive sites as well as the poor quality of some of the observations, which failed to take proper account of background noises, many researchers have dismissed the precursor claims based on such data. Nevertheless, as pointed out by King (1986) and Ma *et al.* (1990), the difficulty may be partly the result of unrealistic modeling of an earthquake (which occurs in an inhomogeneous crust) by a dislocation in a homogeneous and elastic half-space. If the crustal heterogeneity and a large-scale, episodically increasing tectonic stress field are taken into consideration, the above-mentioned features can be reasonably understood, as discussed in the next section.

3. Mechanisms for Earthquake-related Hydrologic and Geochemical Changes

The Earth's crust contains numerous pores and fractures filled with water, gas, and other fluids that have different chemical compositions at different places. When the crust is deformed in the tectonic process of earthquake generation, the fluids of different chemical composition, especially those in the fault and other weak zones, may be forced to migrate and cause the associated hydrological and geochemical changes.

Several mechanisms were proposed to explain the hydrologic and geochemical changes (at the sensitive sites): increased upward flow of deep-seated fluids to the monitored aquifers or shallow holes; squeezing of gas-rich pore fluids out of the rock matrix into the aquifers; mixing of water from other aquifers through tectonically created fissures in the intervening barriers; increased rock/water interactions; and increased gas emanation from newly created crack surfaces in the rock to the pore fluids (King, 1986; Thomas, 1988).

Some of the explanations were tested by laboratory studies of crushed rock samples and by field studies of underground explosions and groundwater pumping (e.g., Brace and Orange, 1968; Giardini *et al.*, 1976; Honda *et al.*, 1982; Kita *et al.*, 1982; King, 1986; King and Luo, 1990). Most of the laboratory studies involve the prefailure phenomena of volume increase of the specimen and stable sliding along planes of weakness. When a rock specimen is subjected to increasing uniaxial or triaxial compression, it commonly begins to show nonelastic volume increase (dilatancy) at a stress level somewhat below the failure stress due to increasing number and size of microcracks/fissures created in the specimen. The same phenomena were presumed to be occurring only at/near earthquake sources and responsible for the generation of various geophysical and geochemical precursors. However, diligent searches of earthquake-related dilatancy has so far failed to produce credible evidence for its occurrence in nature. Also this hypothesis cannot explain why some earthquake-related

changes were observed in certain locations at large epicentral distances but not at other locations closer to the Earthquake. As noted above, to account for such observations, one needs to invoke inhomogeneity of the crust as well as a broadscale and gradually and episodically increasing seismotectonic-deformation field. [Such a field is suggested by the frequent observation of episodic increase of earthquake activity over broad areas (King, 1986; Ma *et al.*, 1990).] Under such a condition, strain may concentrate along some faults and weak zones, where voids and fluids abound, and local dilatancy may occur at the forthcoming-earthquake source as well as at certain sensitive sites where the preexisting stress is near the critical level for the occurrence of fissures and fluid flow.

In a related group of studies, many seismogenic faults, including some buried ones, were found to show spatial anomalies, such as higher concentration of various terrestrial gases (radon, helium, hydrogen, mercury vapor, carbon dioxide, isotopic ratios, etc.) in groundwater and soil air (e.g., King, 1986; Ma, 1990; King *et al.*, 1996). This kind of observation suggests that seismogenic fault zones may be paths of higher fault-parallel permeability such that underground gases from depth may escape to the surface.

4. Origin and Migration of Fluids in the Crust

To help readers better understand the literature on earthquake-related hydrologic and geochemical changes, we review briefly here the current knowledge of origin and migration of subsurface fluids based on studies of a number of so-called tracers (e.g., Fyfe *et al.*, 1978; Ozima and Podosek, 1983; Faure, 1986; Jamtveit and Yardley, 1997).

4.1 Hydrogen and Oxygen Isotopes

A most useful set of tracers to examine the origin and migration of water and other fluids in the crust is the isotopic ratios of hydrogen and oxygen. Hydrogen has a stable isotope called deuterium, D or (^2H), whose abundance in natural water is about 0.16% of total hydrogen. Oxygen consists of three stable isotopes, ^{16}O , ^{17}O , and ^{18}O , with corresponding abundances in natural water of about 99.76%, 0.074%, and 0.20%, respectively. Since changes in these isotopic ratios are usually very small, researchers commonly express the deviations of isotopic ratios in their water samples relative to some standard samples in units of "permil" as follows:

$$dR = [(R_A/R_S) - 1] \times 1000 \quad (1)$$

where R_A and R_S are isotopic ratios of the sample and the standard, respectively. For hydrogen isotopes, $R = \text{D}/\text{H}$, and for oxygen isotopes, $R = ^{18}\text{O}/^{16}\text{O}$. (^{17}O , being less abundant, is usually not measured because of the analytical difficulty.)

In both cases, sea water (Standard Mean Ocean Water, SMOW) is used as a standard.

Natural waters are generally considered as a mixture of three components: oceanic, meteoric, and magmatic. Sea water evaporates from the ocean surface to the atmosphere, is transported in the atmosphere as water vapor by the wind, is condensed to liquid (rain) or solid (snow), and then falls on the Earth's surface as meteoric water. Part of the meteoric water flows to rivers and lakes, and eventually back to the sea. Other parts of the meteoric water penetrate into the soil, some to greater depths, and circulate through rocks to form deep aquifers of mineral or geothermal waters.

Hydrogen and oxygen isotopic ratios in meteoric waters vary considerably due to the kinetic isotope effect during evaporation and condensation. Craig (1961) analyzed these ratios in water samples gathered from rivers, lakes, rain, and snow all over the world; he found that the ratios follow a linear relationship, which is called the meteoric-water line, as follows

$$dD = 8 d^{18}O + 10 \quad (2)$$

The slope of this line can be explained by the ratio of the isotopic fractionation factor of hydrogen to oxygen during condensation of water at a temperature of 25°C, and it has a weak dependence on temperature. The constant term is related to the difference in diffusion velocity of hydrogen and oxygen isotopes and therefore depends on the speed of evaporation at the sea surface (Dansgaard, 1964). Thus, both the slope and the constant term in the above empirical relation can have regional differences, as well as seasonal variations at a given place.

A large part of the magmatic water is believed to be recycled, from subducted oceanic crust as described below. Some sea water is trapped in the ocean-floor sediments as pore water or fixed in oceanic crust to form hydrous minerals. Upon subduction of the sea floor toward the Earth's mantle, the pore waters in the sediments are squeezed out by consolidation at relatively shallow depths, whereas the hydrous minerals in the altered oceanic crust are decomposed as the plate penetrates to greater depths where the temperature and pressure are sufficiently high. The liberated water then tends to migrate upward through the upper mantle and crust to the Earth's surface, because of its lower density than the surrounding rocks. The magmatic water is the water located in deep crust and mantle in equilibrium both chemically and isotopically with surrounding rocks and/or silicate melt.

Some magmatic water may be derived from "juvenile" water, which has never been to the Earth's surface before. By using the hydrogen and oxygen isotopic ratios, it is difficult to distinguish the juvenile water from the recycled water in isotopic equilibrium with the surrounding rocks.

The hydrogen and oxygen isotopic ratios of magmatic waters are usually in the following ranges: $dD = -80$ to -40 per mil; $d^{18}O = +5$ to $+10$ per mil, which are distinctly

different from those of sea and meteoric waters. Thus hydrogen and oxygen isotopic ratios can be used to tell the origin, or the mixing ratios of the three origins, of groundwater.

Tectonic activities including the earthquake-generating processes are intimately related with large-scale migration of groundwater. Careful examinations of hydrogen and oxygen isotopic ratios of deep groundwater samples can greatly improve our understanding of such migration and its relation to earthquakes.

4.2 Dissolved Noble Gases

Another set of tracers useful for studying the origin and migration of waters in the crust is the dissolved noble gases, such as helium. The origin and geochemical cycle of helium are fairly simple, since helium is chemically inert and nonbiogenic. Helium has two isotopes, ^3He and ^4He . Most ^3He released from the solid earth is primordial, i.e., believed to have been incorporated when the Earth was formed 4.6 billion years ago. In contrast, most ^4He is radiogenic, continuously produced by decay of uranium (^{238}U , which has a half-life of 4.5×10^9 y) and thorium (^{232}Th , half-life 1.4×10^{10} y) in the crust and mantle throughout the Earth's history. The terrestrial samples have generally very small $^3\text{He}/^4\text{He}$ ratios, less than 5×10^{-5} (Ozima and Podosek, 1983); their helium contents are mostly radiogenic.

Helium in the Earth's atmosphere is continuously lost to the outer space because of its light atomic weight. Thus the abundance of helium in the atmosphere remains low (5.2 ppm). As a result, in studies of terrestrial helium, the problem of sample contamination by atmospheric gases is generally unimportant.

The $^3\text{He}/^4\text{He}$ ratios observed in groundwaters vary from 10^{-8} to 10^{-5} . These values are usually considered to result from mixing of three helium components: atmospheric, radiogenic, and magmatic with $^3\text{He}/^4\text{He}$ ratios of 1.4×10^{-6} , on the order of 10^{-8} , and 10^{-5} , respectively. The continental crust is enriched in uranium and thorium, with concentrations several orders of magnitude higher than the oceanic crust and the mantle. Thus the $^3\text{He}/^4\text{He}$ ratios in the continental crust are generally much lower than in the atmosphere. On the other hand, the $^3\text{He}/^4\text{He}$ ratios in the oceanic crust and in volcanic regions, which contain magmatic fluids, are usually much higher than the atmospheric value. Since helium diffuses very slowly in rocks by itself, helium migration in the Earth is essentially controlled by the migration of the fluids in which the helium is dissolved (Torgersen and Clarke, 1987). Thus, the dissolved helium can be a useful tracer for studying the origin and large-scale migration of crustal fluids, including groundwater.

A unique component of ^3He is that produced by the decay of tritium, ^3H . Tritium has a half-life of 12.26 y and was produced mainly by nuclear explosions beginning in the 1950s. Since then, the meteoric water has contained trace amounts of

tritium. Once the meteoric water penetrates into the crust, tritium decays monotonically to ^3He , and enhances the dissolved $^3\text{He}/^4\text{He}$ ratio in proportion to its residence time. Thus the tritium-generated helium accumulation in groundwater can be used as a chronometer, giving groundwater age since precipitation (Torgersen *et al.*, 1977):

$$T = \ln(^3\text{He}_{\text{excess}}/t + 1)/l \quad (3)$$

where T is the age, $^3\text{He}_{\text{excess}}$ is the amount of excess ^3He due to the decay of tritium, t is the tritium content in the water, and l is the decay constant of tritium (0.05654 y^{-1}).

Another noble gas commonly used as a geofluid tracer is argon. In contrast to helium, the argon isotopes have large atomic weights and thus can accumulate in the atmosphere (to about 0.9%). Argon has three stable isotopes, ^{36}Ar , ^{38}Ar , and ^{40}Ar , with relative compositions in the atmosphere of 0.34%, 0.06%, and 99.6%, respectively. The most abundant Ar isotope, ^{40}Ar , is the decay product of ^{40}K (with a half-life of $1.25 \times 10^9 \text{ y}$). The other isotopes, ^{36}Ar and ^{38}Ar , are primordial and are thought to have largely degassed in Earth's early catastrophic events.

Presently the $^{40}\text{Ar}/^{36}\text{Ar}$ ratio is 295.5 in the atmosphere, and generally much higher in the Earth's interior due to accumulation of ^{40}Ar produced by ^{40}K decay. Like ^4He , ^{40}Ar in the Earth's interior is mainly transported by subsurface fluid migration. Thus the $^{40}\text{Ar}/^{36}\text{Ar}$ ratio in geofluids can be used as a tracer for their (large-scale) migration (Torgersen, 1989).

The heaviest noble gas, radon, has been used as an important geochemical tracer for fluid migration on a small scale in both time and space, and for studying degassing phenomena at/near the Earth's surface. Radon has no stable isotopes, but has three radioactive isotopes: ^{222}Rn (half-life, 3.825 days), ^{220}Rn (half-life, 54.5 sec), ^{219}Rn (half-life, 3.92 sec). Among these isotopes, ^{222}Rn has the longest half-life and is of the most geochemical interest. It is a product of the ^{238}U decay series. When decaying under equilibrium condition, it emits three alpha rays, two beta rays, and numerous gamma rays. ^{220}Rn , also called thoron, is a decay product of thorium, ^{232}Th . Minute amounts of radon can be measured easily and accurately by counting the corresponding radioactivities on a continuous basis (e.g., Noguchi and Wakita, 1977). This and other advantages have made radon one of the most important parameters studied for earthquake prediction. Because of its half-life of 3.825 days, ^{222}Rn is considered an ideal parameter to study in the search of short-term (days) premonitory signals.

5. Recent Observations

Observations of earthquake-related hydrologic and geochemical changes were made more carefully during the past decade, by using better instruments (i.e., continuously recording, higher

sensitivity and reliability) and by giving proper consideration to background noise, such as changes caused by changing barometric pressure and solid-earth tide. The results, however, still show largely the same characteristic features observed earlier: (1) sensitivity of monitoring sites, even only meters apart, can be greatly different; (2) at near-field sites, some recorded earthquake-related changes are consistent with poroelastic dislocation models of earthquakes; (3) however, co- and post-seismic changes can be recorded for many moderate and large earthquakes at some sensitive sites too large (up to about 1000 km for magnitude 8) to be explained by the poroelastic models; (4) recorded premonitory changes are relatively few and less certain; (5) sensitive sites are usually located on or near active faults and characterized by some near-critical hydrologic or geochemical condition (e.g., permeability that can be greatly changed by a slight shaking or stress change); (6) the earthquake-related changes recorded for different earthquakes at a sensitive site are usually similar, regardless of the earthquake's location and focal mechanism; and (7) the sensitivity may change with time as the crustal stress changes (e.g., Silver and Vallette-Silver, 1992; Roeloffs, 1996, 1998; Wakita, 1996; King *et al.*, 1999, 2000).

A notable example of the long-distance triggering effect of large earthquakes is the observation of numerous earthquakes triggered by the magnitude 7.3 Landers, California, earthquake in 1992. The triggered earthquakes were located in geothermal and volcanic areas across the western United States at distances of up to 1250 km (Hill *et al.*, 1993). No significant earthquakes were triggered, however, in the nearby San Andreas fault segments outside the aftershock area. Such a long-distance triggering phenomenon cannot be explained by the small static stress changes calculated from elastic models of the earthquake, but can be attributed to seismic-wave-triggered fluid movement in and near some critically loaded faults in the triggered areas. Indeed, various hydrologic phenomena, including gas bubbling, increased spring discharge, and groundwater-level changes, were observed after the earthquake in many of such areas (Roeloffs, 1996).

Another recent example of earthquake-related changes in crustal-fluid movement is provided by the study of eruption-interval changes at a nearly periodic geyser located not far from the San Andreas fault north of San Francisco, California (Silver and Vallette-Silver, 1992). Coseismic and precursory changes were detected for three earthquakes at epicentral distances of 100–200 km, including the magnitude 6.9 Loma Prieta earthquake in 1989.

In Parkfield, California, where an earthquake-prediction experiment has been in progress for two decades, steplike coseismic water-level drops were recorded at four wells at the time of the magnitude 5.8 Kettleman Hills earthquake about 35 km away (Roeloffs and Quilty, 1995). Detailed study of the data also show small water-level changes beginning three days before the earthquake in two of the wells. Also at a shallow well, coseismic water-level rises were observed at the time of

three local and five distant earthquakes (as far away as 730 km for a magnitude 7 event) (Roeloffs, 1998).

In Japan, the University of Tokyo has maintained a network of about a dozen continuously monitored hydrologic and geochemical stations along the nearby Pacific coast since 1978 (Wakita, 1996). One of the stations on the Izu peninsula recorded a clear radon-concentration change before the nearby magnitude 7.0 Izu-Oshima-Kinkai earthquake in 1978. Similar preseismic changes in groundwater level, temperature, and strain were observed at three other sites, all at epicentral distances of 25–50 km beginning a month before the event. Also, over the years, only two of the stations (one for radon and one for water level) have been found to be sensitive to distant earthquakes (such as a magnitude 8.1 event 1200 km away). The sensitivity was found to vary with time, probably as the regional stress varies.

Co- and preseismic changes in groundwater level/discharge, geochemistry, radon concentration in groundwater and atmosphere, and strain were observed at several locations up to 220 km away from the magnitude 7.2 Kobe earthquake in 1995, although the earthquake occurred outside of the Japanese intensive-study area of Tokai. Most of the preseismic changes were recorded within the ultimate aftershock zone beginning 3 months before the event (Igarashi *et al.*, 1995; King *et al.*, 1995; Tsunogai and Wakita, 1995; Yasuoka and Shinogi, 1995; Sugisaki *et al.*, 1996). In a questionnaire survey conducted shortly after the earthquake, Koizumi *et al.* (1996) found postearthquake water-level/discharge changes at many sites (among many more sites without such changes) at epicentral distances up to about 300 km. The distribution pattern of these changes cannot be explained satisfactorily by volumetric strain changes derived from dislocation models of the earthquake.

King *et al.* (1999) studied water-level data continuously recorded over a period of ten years at a closely clustered set of 16 wells within 400 m of a fault in Tono, central Japan (Fig. 1). They found that earthquake-related co- and postseismic changes at wells on different sides of the fault show very different features (Fig. 2). The difference is attributable to a seismically induced permeability increase of the normally impermeable fault-gouge zone, which has sustained a considerable hydraulic gradient across the fault. One of the wells showed coseismic changes for more than 20 local and distant earthquakes, including a magnitude 8 event about 1200 km away (Fig. 3). All the coseismic changes and subsequent recoveries have similar shapes, irrespective of the location and focal mechanism of the earthquakes. This well is located on the higher-groundwater-pressure (north) side of the fault. The high sensitivity is attributable to this well's tapping a high-permeability aquifer connected to one of the high-permeability fracture zones that bracket the impermeable fault-gouge zone. Because of the large hydraulic gradient across the gouge zone, a relatively small seismic shaking (or tectonic stress increase) may introduce some quickly healable fissures in the gouge

FIGURE 1 (a) Location of Tono study area in central Japan and large earthquakes discussed in this chapter. Bold lines indicate boundaries between the converging Pacific Plate on the east and the Eurasian Plate on the west, with the Philippine Sea Plate (south) and North American Plate (north) in between. Earthquakes for which water-level changes were observed at Tono are indicated by solid-segmented beach balls that show earthquake mechanisms; other earthquakes are indicated by beach balls with shaded segments. (b) Same as above for moderate local earthquakes. The location of Tono is indicated by the triangle, and active faults by shaded lines (after King *et al.*, 1999).

FIGURE 2 (a) Coseismic water-pressure changes recorded during March 1997 at five different depths of TH-8 well (with help of packers) located on the higher-groundwater-pressure (north) side of the Tsukiyoshi fault (see Fig. 1c of King *et al.*, 1999). The pressure data P1 through P5 are numbered sequentially upward and plotted on different vertical scales. The arrow indicates the occurrence of the largest local earthquake since 1983, magnitude 5.8 about 50 km away. (b) The same for comparable depths of TH-7 well located on the lower-pressure (south) side of the fault (after King *et al.*, 1999).

FIGURE 3 Coseismic water-level drops (in the middle of the curves) and subsequent recoveries recorded at the sensitive SN-3 well during periods of 30 days. The corresponding earthquake locations are shown in Figure 1 (solid symbols). The changes in (b) are smaller than those in (a); they become apparent only after the barometric-pressure and tidal effects are corrected (after King *et al.*, 1999).

FIGURE 4 Preearthquake water-level changes (in the middle of the 60-day window) recorded at the sensitive SN-3 well for five large distant earthquakes (shown in Fig. 1). The dates of the earthquakes are indicated on the left side of the figure (after King *et al.*, 1999).

FIGURE 5 Magnitude of earthquakes as a function of hypocentral distance from Tono. The solid line indicates an estimated threshold separating earthquakes associated with a resolvable coseismic water-level change at the SN-3 well (solid circles) from those without (open circles). The diamonds indicate earthquakes associated with pre-earthquake changes. For comparison, the dashed lines indicate volumetric strain levels expected from a dislocation model of earthquakes. Note that, following the magnitude 5.8 earthquake on 16 March, 1997, the earthquake on 24 May 1997 did not cause any coseismic change, as it should according to the empirical relation. The apparently decreased sensitivity of SN-3 at this time is attributed to stress relaxation caused by the earlier event (after King *et al.*, 1999).

zone, resulting in a significant temporary permeability increase causing the observed kind of changes. Water level at this well was also found to have shown preearthquake drops for several earthquakes (Fig. 4). Some of the preearthquake drops were later found to be due to human activities (e.g., drilling of holes across the fault, resulting in a cross-fault water flow), but one of them (see Fig. 7 of King *et al.*, 2000), beginning about six months before a magnitude 5.8 earthquake 50 km away, the largest local event since 1983, may be truly premonitory in nature (King *et al.*, 2000). The sensitivity of the well showed a temporary decrease during a one-year period after the earthquake, presumably due to temporary relaxation of stress to sub-critical level by the earthquake (Fig. 5).

Many gas-geochemical surveys were conducted across active faults worldwide. Most of the results show fault-related spatial anomalies (e.g., King *et al.*, 1996). Based on measurements of radon, CO₂, and O₂, King *et al.*, attributed such anomalies along a fault in California to an upward flow of soil air in the high-permeability fracture zones of the fault.

6. Discussion and Conclusions

Hydrologic and geochemical parameters, like geophysical parameters, have been studied extensively during the past several decades in search of possible premonitory changes useful for earthquake prediction. Nevertheless, relatively few significant precursors have been recorded and the results are still inconclusive. The enormous complexity of the challenge has not been met by matching amount of funding and manpower. Not knowing where the next destructive earthquakes are going to strike, it has been extremely difficult to deploy a sufficient number of reliable instruments at appropriate locations long enough to record sufficient background data and to catch a significant number of possibly true precursors. (So far few significant earthquakes have occurred in areas of intensive studies.) Maintaining monitoring efforts over long periods of time is difficult because of some inevitable problems, such as funding uncertainty, personnel change, and instrument failure. Other difficulties arise from the inaccessibility of fluids at seismogenic depths, inhomogeneity of the crust (and the resultant problem of sensitive versus insensitive sites), and the lack of realistic models that take the inhomogeneity of the crust into account.

In spite of the above-mentioned difficulties, recent studies have shown some credible premonitory changes as well as many co- and postseismic changes. These changes were recorded at a relatively few sensitive sites among many insensitive ones. The sensitive sites can be located hundreds of kilometers away from the corresponding earthquakes, and they are commonly characterized by certain near-critical stress conditions where the local permeability can be greatly changed by a small stress increment or seismic shaking. The

sensitivity of a sensitive site may change with time, depending on how close the preexisting stress is to the critical level for fissure production.

Because of the lack of sufficient data to meet the enormous challenge, it seems too early to conclude whether earthquakes are predictable or not in general terms. To overcome the above-mentioned difficulties, a prediction effort should: adopt a multistage, multisite, and multidisciplinary approach; use sensitive telemetered instruments of good long-term stability and fine time resolution; deploy them at sensitive locations long enough to recognize normal background noises and to catch enough target earthquakes; develop sufficiently realistic geophysical and geochemical models for the heterogeneous crust; and use appropriate statistical methods for objective data analysis.

1. Introduction

The study of anthropogenic seismicity began when earthquakes were first felt in Johannesburg in 1894 (McDonald, 1982); by 1908 these events had been attributed to the Witwatersrand gold production, which had commenced in 1886 (Cook *et al.*, 1965). Mine seismicity began to be recognized in Europe in about the same era. The first seismological observatory for monitoring these phenomena was established in Bochum in the Ruhr coal basin, Germany, in 1908 and the first seismic network was installed in the Upper Silesia coal basin, Poland, in the late 1920s (Gibowicz and Kijko, 1994).

Since then, many other types of induced and triggered earthquakes have been either recognized or, at least hypothesized. Seismicity associated with petroleum production became apparent in the early 1920s, with reservoir impoundment in the late 1930s, with high-pressure liquid injection at depth in the mid-1960s, and with natural gas production in the late 1960s. Currently debated is the possible connection between major petroleum or natural gas production and large earthquakes at midcrustal depths.

As used here, the adjective “induced” describes seismicity resulting from an activity that causes a stress change that is comparable in magnitude to the ambient shear stress acting on a fault to cause slip, whereas “triggered” is used if the stress change is only a small fraction of the ambient level (e.g., Bossu, 1996; McGarr and Simpson, 1997). By “stimulated” we refer generally to seismicity either triggered or induced by human activities. As will be seen, most of the case histories reviewed here entail triggered rather than induced seismicity.

Our assumption is that a wide variety of examples of stimulated seismicity can provide independent perspectives regarding the essential problem of the causes of earthquakes

(Simpson, 1986). Accordingly, we review case histories exemplary of a broad spectrum of causative mechanisms and ranging from obvious to speculative in the correlation between earthquakes and specific human activities. Hopefully, by surveying a representative cross section of such earthquakes we can gain general insights. To this end, it is important to establish the similarities and differences in the mechanisms responsible for the various types of stimulated earthquakes. Thus, progress in understanding one type of artificial earthquake can be of use in understanding other types and perhaps interactions between natural earthquakes as well (see Harris, 1998; Chapter 73 by Harris).

The mechanisms that have been invoked to account for anthropogenic seismicity include changes in the state of stress, pore pressure changes, volume changes, and applied forces or loads. These mechanisms, of course, are not all independent. Often, for a particular case, the analysis of several mechanisms can provide different perspectives regarding the resulting seismicity. Ideally, if we understand these mechanisms well enough and we also know the background crustal state (tectonic setting), then we can forecast both where triggered seismicity will occur and the maximum likely earthquake magnitude.

Figure 1a,b introduces the types of seismicity reviewed here starting with mining-induced earthquakes, for which cause and effect are established, and ending with large-magnitude seismicity at midcrustal depth whose association with shallow-level hydrocarbon production is only speculative. In general, triggering is a plausible explanation for earthquakes if the corresponding perturbation can be shown to have shifted a fault toward failure at a time that can account for the onset of seismicity. This task is easier where natural seismicity is low and a chance correlation in time and space between a possible trigger and seismicity is unlikely.

FIGURE 1 (a) Schematic view of seismicity stimulated by quarry, deep mining, and reservoir impoundment. For each case, the important mechanisms for causing seismicity are indicated. Quarries and deep-level mining cause the water table to be depressed because of pumping operations to prevent flooding. (b) Schematic view of seismicity stimulated by liquid injection at depth, which can raise the pore pressure on faults in the environs, and earthquakes caused by the exploitation of major oil and gas fields. Oil or gas production reduces the pore pressure within the reservoir, causing contraction and induced stress changes in the environs. These stress changes can result in a variety of focal mechanisms as indicated. On a larger scale, production can change the crustal loading substantially resulting in major earthquakes at midcrustal depths. A thrust faulting earthquake tends to thicken the crust so as to offset the vertical force imbalance due to production.

2. General Considerations

2.1 Ambient State of Stress and Pore Pressure

In situ stress measurements made in a variety of tectonic settings, both active and inactive, indicate, almost invariably, that the ambient state of stress in the continental crust is quite close to the depth-dependent strength of the crust estimated from laboratory experiments (e.g., Zoback and Healy, 1984; Brudy *et al.*, 1997). Moreover, these same investigations reveal that the ambient pore pressure is nearly always close to hydrostatic. Laboratory estimates of crustal strength

(e.g., Brace and Kohlstedt, 1980) are based on stick-slip friction experiments as extrapolated to conditions anticipated at depth in the crust. That is, if the upper seismogenic crust is pervasively faulted then frictional sliding across these faults [Byerlee's (1978) law] will limit the strength of the crust.

The strength of a fault, or the shear stress τ required for failure, can be expressed as

$$\tau = \tau_0 + \mu(\sigma_n - p) \quad (1)$$

where τ_0 is the cohesion, μ is the coefficient of friction, σ_n is the normal stress across the fault and p is the pore pressure within the fault zone. Laboratory measurements of μ are generally in the range 0.6–1.0 (Byerlee, 1978; Dieterich, 1979). Thus, for a given state of stress, the strength of a fault would depend on its orientation, pore pressure, and cohesive strength. In estimating crustal strength it is often assumed that (1) faults exist in the crust that are optimally oriented for failure, (2) the water table is at the surface (hydrostatic pore pressure), and (3) the cohesive strength can be neglected.

2.2 Stress and Pore Pressure Changes Required to Cause Earthquakes

Triggered or induced seismicity occurs when the mechanical state of the seismogenic crust is sufficiently perturbed to cause a fault to fail. As indicated by Eqn. (1), failure can occur either because the stress τ loading the fault increases or the strength of the fault is reduced due to a decrease in the normal stress σ_n or an increase in the pore pressure p .

Figure 2 shows a ternary diagram in which these three components (σ_n , τ and p) form a field in which can be placed different types of induced and triggered seismicity, depending on the dominant cause. In some cases, the isolation of a single mechanism is simple (e.g., increases in pore pressure cause injection-related seismicity). In others (e.g., reservoir triggering) the relationship is more complex. More than one parameter may be involved (shear stress and pore pressure) or parameters may be coupled (e.g., stress and pore pressure). While care should be taken not to oversimplify what is often a complex process, this figure can help as a reference in the following discussion to identify the dominant factors influencing failure.

For a number of the case histories to be discussed here, the stress changes required to trigger seismicity, as well as the corresponding seismic stress drops (of the order of 1 MPa), are small fractions of the shear stress acting to cause fault slip (e.g., McGarr and Simpson, 1997); indeed, numerous studies, some of which are reviewed here, lead to the conclusion that stress changes as small as 0.01 MPa [Eq. (1)] may trigger earthquakes. This general observation is consistent with the idea that the crustal state of deviatoric stress tends to be nearly as high as the crustal strength (e.g., Zoback and Harjes, 1997; Grasso and Sornette, 1998). The exception to this

FIGURE 2 A simplified classification of three of the mechanisms controlling stimulated seismicity [see Eq. (1)]. Surface quarries, deep mines and regional earthquakes cause increases in seismicity primarily through modifications to the elastic stress field. Increased pore pressure is the dominant factor for liquid injection at depth. Reservoir loading can entail changes in all three parameters to stimulate earthquakes. Oil and gas field compaction primarily results in changes in the state of stress within the seismogenic rockmass surrounding the reservoirs. (Adapted from Figure 1 of McGarr and Simpson, 1997.)

generalization is mining-induced seismicity (Fig. 1) for which the stress changes causing the earthquakes are of the same order as the ambient crustal stresses loading the mine workings, as will be described.

2.3 How Much Seismic Deformation?

Given that seismicity occurs in response to specific changes in stress or pore pressure [Eq. (1)], then the next question entails the amount of seismic deformation that results. This is an important question because both the maximum magnitude and the seismic hazard are well correlated with the total seismic deformation.

Perhaps the most straightforward factor influencing the potential for seismic deformation is the size of the region over which an activity (e.g., gas production) takes place, as will be illustrated later. Volume changes associated with mining, liquid injection at depth and petroleum exploitation (McGarr, 1976; Pennington *et al.*, 1986) provide another means of estimating the potential seismic deformation. Similarly, large-scale oil and gas exploitation can remove mass and thereby change the crustal loading resulting in an isostatic imbalance; it is straightforward to calculate the seismic deformation needed to restore isostatic balance to the region (McGarr, 1991).

It is important to note that we can only estimate the potential for seismic deformation resulting from a particular human activity, which is not the same as predicting the ensuing seismic deformation. There are, needless to say, many activities that have the potential for producing sizable earthquakes (e. g., large

impounded reservoirs) that, in fact, result in little or no detected seismicity. This issue is returned to later.

2.4 Triggered Seismicity in Stable Continental Regions and in Tectonically Active Regions

Even though deformation rates in stable continental regions within the plates are so low that they cannot yet be measured with the current $\approx 10^{-10}$ geodetic resolution (Argus and Gordon, 1996), earthquakes nonetheless occur there which suggests that deformation rates are finite and perhaps coherent over large regions of the continents (Sbar and Sykes, 1973). Faults that can be associated with this seismicity tend to be small and to have little accumulated displacement (Adams *et al.*, 1991; Crone *et al.*, 1992; Machette *et al.*, 1993; Seeber *et al.*, 1996). Geologically, they do not stand out from many other faults scattered over these stable regions. Seismicity and geology, therefore, suggest that potential sources of earthquakes are ubiquitous in these areas in spite of their tectonic stability (Seeber *et al.*, 1996). This is consistent with many sets of *in situ* stress data (e.g., Brudy *et al.*, 1997) indicating states of stress close to the failure state for both stable and tectonically active regions.

Although anthropogenic seismicity in different tectonic environments has not been rigorously compared, it seems higher in stable continental regions because of the combination of low strain rate, which yields a low level of natural seismicity, and a near-failure state of stress, which is the key factor in the occurrence of triggered earthquakes. Assuming that all other factors are equivalent, including the average proximity of the stress to failure, similar absolute levels of triggered seismicity are expected in tectonically stable regions and at plate boundaries. Because of the vast difference in rates of natural seismicity, however, artificially triggered seismicity appears to be far more significant in stable regions than in plate boundary settings.

The tendency of many natural earthquakes in stable tectonic settings to nucleate in the upper few kilometers of the crust (e.g., Ungava, 1990; Adams *et al.*, 1991; Mekering, 1968; Vogffjord and Langston, 1987; Tennant Creek, 1988; Choy and Bowman, 1990; Marryat Creek, 1986; Fredrich *et al.*, 1988) is another factor that may contribute to the relative importance of artificially triggered earthquakes in these areas. Presumably the seismogenic crust in these tectonically stable regions extends to shallow levels and thus may be relatively close to engineering activities that might cause seismicity, such as quarry operations. In contrast, most significant earthquakes in active areas tend to nucleate below the upper few kilometers of the crust which are thought to be too fractured and weak to accommodate significant elastic energy (e.g., Scholz, 1990). Thus the near-surface perturbations from engineering activities may coincide more closely with the seismogenic crust in stable than in active tectonic settings.

2.5 Monitoring Induced and Triggered Earthquakes and their Causes

In contrast to poorly understood natural seismotectonic processes, mechanical changes caused by engineering operations in the seismogenic depth range of the crust can be assessed in some detail in terms of their potential for induced and triggered seismicity. The predictability of triggered seismicity offers the opportunity for a systematic approach to designing seismic experiments that can provide unique insights regarding the earthquakes, their causes and their effects, particularly in areas where natural seismicity is low. Monitoring should start before the perturbation so that an onset of unprecedented seismicity, if it occurs, can be recognized and compared to the evolution of any forcing function. Furthermore, the monitoring needs to continue after the end of the engineering operation because the strongest perturbation may stem from a delayed rise in fluid pressure. Additionally, these observations need to include not only high-resolution earthquake ground motion data, but also geodetic, pore pressure, and water level data, as well as pertinent industrial and engineering parameters.

In many of the early cases of earthquakes triggered near dams, some ambiguity existed because of the lack of detailed monitoring before impounding of the reservoir (e.g., Lake Mead, Roeloffs, 1988). As the possibility of triggered seismicity has become more widely appreciated and acknowledged, it is becoming more common to have seismic stations installed and operating during the early development stages so that a clear picture of background seismicity is available.

2.5.1 Earthquake Monitoring

The instrumentation and techniques for observations of induced and triggered earthquakes are similar to those for any local, shallow seismicity (Chapter 17 by Lee). Dense networks of seismometers are required to determine both the temporal evolution of seismicity, including the time-dependent spatial patterns of earthquake locations. Because the onset of triggered seismicity may involve subtle changes in microearthquakes, it is important to have a monitoring system with adequate sensitivity and high location accuracy, so that low-magnitude events can be well recorded. To avoid the signal degradation associated with near-surface site effects, borehole recording using three-component seismometer packages having wide dynamic range and broad bandwidth is highly recommended (e.g., Malin *et al.*, 1988; Abercrombie, 1995).

With regard to data analysis, precise hypocentral locations and magnitude assignments are essential, but there is much more that can be gleaned from the seismograms. In particular, seismic source parameters including source dimension, seismic moment, stress drop, and radiated energy (e.g., Spottiswoode and McGarr, 1975) can provide useful insights for relating industrial operations to the resulting seismicity. For instance, seismic moment tensors have revealed key

information regarding energy budgets of earthquakes and their relationship to mining operations (McGarr, 1992).

Triggered seismicity tends to be close to major engineered structures (dams, wells, mines) and may include damaging earthquakes. Seismic instrumentation deployed on these structures can provide valuable detailed knowledge of their response to strong ground motion.

2.5.2 Monitoring the Causes of Induced and Triggered Earthquakes

If the relationship between the stimulated seismicity and its cause is to be established and understood, it is essential that there be detailed monitoring of the causative agent itself (e.g., water level in reservoirs; pressure and volume of fluids injected or extracted). These data need to be available as time series with sufficient resolution to be compared to the time and size of earthquakes. Measurements of crustal deformation generally have played key roles in relating various human activities to corresponding induced or triggered earthquakes. Such measurements include trilateration, leveling, tilt, and borehole strain. Airborne or space synthetic aperture radar (SAR) interferometry offers new opportunities for detailed monitoring of strain.

2.5.2.1 Reservoirs

To first order, the most obvious parameter to measure at a reservoir is the depth of water at the dam (usually the deepest part of the reservoir). Because of its importance in operation of power plants or irrigation, this parameter is measured precisely and frequently by the dam operator. Daily measurements with a precision of centimeters are usually available. Water volume in the reservoir is also estimated, usually through knowledge of the basin geometry. Often overlooked in studies of reservoir-triggered seismicity is the growth of the reservoir over time and the influence of the reservoir on the regional water table. Less frequently, deep piezometer wells are drilled as part of the assessment of the regional groundwater regime and these may continue to be monitored during exploitation of the reservoir.

2.5.2.2 Liquid or Gas Injection and Extraction

The pressure and volume of fluid in or out of the rock are the key parameters. They are also of prime concern to the facility operator and are carefully monitored. These data are often considered proprietary, however, and so are difficult to obtain because they may have direct economic and liability implications.

2.5.2.3 Mines and Quarries

In cases of seismicity associated with mining or quarrying, the mass of extracted material and the geometry of the excavations are important. In deep mines the opportunity exists to compare seismicity directly with *in situ* stress measurements. Some large mines now include extensive seismic systems as

a safety measure for monitoring rockbursts. In addition to being an important part of the mine operations, the data from these systems can provide information of direct relevance to the nature of induced seismicity and earthquake sources in general. Most mines and quarries require continuous pumping of water to prevent flooding. After they are abandoned, pumping ceases, allowing the water table and pore pressure to rebound to original levels. But, the stress is permanently altered by the mining, leading occasionally to triggered seismicity; we review in the next section a case history of this. It is useful, therefore, to continue monitoring seismicity, water level, and pore pressure after the facility is shut down.

2.6 Can Triggered Earthquakes Be of Use?

Earthquakes can be helpful in several ways. For instance, harmless small earthquakes can give information about large potentially damaging ones. In situations where earthquakes are triggered by known hydromechanical changes, analysis of these events can improve our general understanding of processes leading to earthquakes. As an example, the nucleation process, whereby friction on a fault changes from static to dynamic, is recognized as a key to understanding earthquake physics and to make progress in earthquake prediction (e.g., Dieterich and Kilgore, 1996). In the natural laboratory provided at sites of triggered earthquakes, the nucleation process that occurs between the time of the triggering perturbation and the occurrence of the earthquake can be studied in some detail and the dependence of the nucleation time on the characteristics of the earthquake and of the stress perturbation can be explored (e.g., Harris and Simpson, 1998).

Earthquakes can provide information about the changes in hydromechanics that triggered them. Engineering projects that alter conditions in the crust may consider earthquakes as a threat to the integrity of the operation and as a potential liability, but they may also use them for remote monitoring of physical parameters in their field of operation. Applications of modern seismology to engineering problems may include monitoring stress parameters including pore pressure effects (e.g., Reasenber and Simpson, 1992), illuminating the structure and kinematics of active faults (e.g., Seeber and Armbruster, 1995) and resolving bulk properties such as anisotropy and anelasticity (Hough *et al.*, 1999). Earthquakes may also illuminate flow paths as shear failure tends to increase permeability on joint or fault surfaces (Brown and Bruhn, 1996). Thus seismology is becoming a tool for monitoring hydrocarbon fields, hydrothermal energy recovery systems, and waste-fluid disposal in deep wells. Finally, we note that monitoring of microearthquakes in mines provides information that can influence management decisions regarding production operations so as to enhance underground safety by taking seismic hazard more fully into account.

2.7 Liability for Induced and Triggered Earthquakes

From a scientific perspective, the liability aspect of induced or triggered earthquakes largely entails disadvantages to anyone trying to understand these earthquakes (in contrast to someone seeking to assign blame for them). In most cases, sincere efforts to work closely with professional staff at an engineering operation that could cause or is experiencing triggered or induced seismicity will result in productive co-operation. In some cases, however, especially in areas of high risk, concerns over litigation can stifle cooperation. For example, the potential for litigation may cause industry to be reluctant to release data that, although scientifically valuable, might be used in a court of law to establish liability. Similarly, industry may hesitate to even record data (e.g., seismic) that could be used for purposes of litigation. Moreover, collegial relations between scientists may be compromised by legal proceedings and the exchange of scientific information curtailed. Although self protection by private enterprise is understandable, society in general and the scientific community in particular suffer the disadvantage of being denied potentially beneficial information. Such situations can be mitigated by government regulatory agencies which can apply both "carrot" and "stick." For instance, industrial activities that tend to cause seismicity might be required to collect and release pertinent data. The "carrot" may entail a broader distribution of responsibility for the seismic risk involved in engineering operations which are vital to society. Scientists can also offer a "carrot" to industrial management in the form of improved understanding of the interaction between natural processes and engineering operations that would improve the basis for production decisions from both the economic and the liability standpoint. For the reader interested in a comprehensive discussion of legal issues associated with anthropogenic earthquakes, we recommend the article by Cypser and Davis (1994).

3. Case Histories of Stimulated Seismicity

The following examples have been chosen from many different regions to illustrate various mechanisms that relate human activities to stimulated seismicity. These case histories begin with mining-induced earthquakes for which the relationship between mining and earthquakes is unequivocal, and end with major earthquakes at midcrustal depths beneath oil and gas fields where a connection between the production and the seismicity is controversial.

3.1 Mining Seismicity

We review here five examples of mining seismicity, selected so as to illustrate the effects of factors such as depth, scale, state of

stress, pore pressure, and mining technique. A vast literature has accumulated in the last four decades about mining-induced earthquakes (e.g., see bibliography in Gibowicz and Kijko, 1994). This type of seismicity is arguably better understood than other types and, thus, is of particular interest regarding insights into the causes and mechanisms of natural earthquakes. That is, earthquakes caused by mining appear to be largely the same phenomena as natural crustal earthquakes but, as reviewed here, can be analyzed more confidently in terms of causative forces, energy budgets, and hypocentral circumstances.

3.1.1 Deep-level Gold Mining in South Africa

The Witwatersrand gold fields, where the study of induced and triggered earthquakes began early in the 20th century (e.g., Cook *et al.*, 1965), currently involve gold production at depths between 2000 and 4000 m in an extensional, but inactive, tectonic setting. In these mines, gold production is achieved by excavating subhorizontal tabular stopes, with initial widths a little greater than 1 m and lateral extents generally in the range of 100 m to several km. The high level of seismicity, typically within several hundred meters of the active mine faces, is associated with the substantial stress changes in the brittle strata abutting the stopes. The source of energy for this process is the collapse of the tabular voids due to the considerable overburden stress (Cook, 1963; Cook *et al.*, 1965; McGarr, 1976, 1993); magnitudes occasionally exceed 5 (Fernandez and van der Heever, 1984) and levels of ground velocity, especially in the hypocentral environs, can be in excess of several meters per second and highly damaging (Wagner, 1984; McGarr, 1993; Ortlepp, 1997).

The rate of seismic deformation, as measured by estimating seismic moments, has been related quantitatively to the rate of ore production and the attendant stope collapse (McGarr, 1976). Maximum magnitudes or moments, however, are influenced by the mining techniques. Irregular mine geometries give rise to the largest earthquakes (e.g., McGarr and Wiebols, 1977; Gay *et al.*, 1984), a point which is returned to later.

The stress changes that cause the seismicity often involve increases in the shear stress as well as decreases in the normal stress acting on the fault plane and can be estimated using various methods (e.g., Cook, 1963; Cook *et al.*, 1965; McGarr *et al.*, 1975; McGarr, 1993). These changes are substantial, of the order of 25 MPa, which is about an order of magnitude greater than typical stress drops of 0.5–5 MPa for these events (Spottiswoode and McGarr, 1975; Spottiswoode, 1984). Accordingly, these earthquakes are induced, not triggered.

Similarly, volumes of stope collapse associated with mining-induced earthquakes can be used to calculate the energy released by these events for comparison with the energy radiated seismically. It turns out that at most a few percent of the released energy appears in the seismic radiation, which implies

that nearly all of the available energy is consumed in overcoming fault friction (e.g., McGarr, 1976, 1994; Spottiswoode, 1980).

The largest mining-induced earthquake recorded in the South African gold fields occurred in 1977 in the Klerksdorp mining district and was assigned a magnitude of 5.2 (Fernandez and van der Heever, 1984; Gay *et al.*, 1984). At that time this district included four large mines covering an area approximately 27 km in extent (Gay *et al.*, 1984), with gold-bearing reefs at depths somewhat in excess of 2000 m; in this district, mine layouts tend to be somewhat irregular because preexisting normal faults offset the gold-bearing horizons often by several hundred meters.

3.1.2 Underground Research Laboratory (URL), Canada

The URL, situated in southeastern Manitoba within the Lac du Bonnet precambrian granite, was established to test the feasibility of nuclear waste storage. This facility, involving a shaft more than 400 m deep and horizontal tunnels extending out at several different levels, has been the site of intense geotechnical and seismological monitoring (Talebi and Young, 1992; Martin and Young, 1993). This example provides some interesting contrasts to that of the deep mines in South Africa with regard to depth (400 m vs. several kilometers), tectonic setting (compressional instead of extensional), and scale (several meters vs. several hundred meters or greater). The seismicity is tightly coupled to the excavation of both shaft (Gibowicz *et al.*, 1991) and tunnels (Martin and Young, 1993). Small events, with magnitudes in the range -4 to -2 , are located near the advancing shaft bottom and tunnel faces (Feignier and Young, 1993). In the vicinity of the seismicity caused by shaft development at depths near 400 m (Gibowicz *et al.*, 1991), the ambient principal stresses $[(S_1, S_2, S_3) = (55 \text{ MPa}, 48 \text{ MPa}, 14 \text{ MPa})]$ are oriented approximately northwesterly, southwesterly, and vertically (Martin and Young, 1993). The seismogenic zones are within several meters of the shaft sidewall where S_1 has been amplified by a factor of about 2, from 55 to 110 MPa (McGarr, 1994). Thus, the shaft, with a diameter of 4.6 m, interacts with the horizontal principal stresses to produce earthquakes with magnitudes as high as -1.8 (Gibowicz *et al.*, 1991).

3.1.3 Exceptionally Large Events Caused by "Room and Pillar" Mining

An association between irregular mine geometries and large magnitude events was mentioned above. The 1989 Volkershausen, Germany, rockburst is a spectacular illustration of this effect. This event, with a magnitude of 5.4 (Knoll, 1990; Bennett *et al.*, 1994) occurred in the Ernst Thaelmann Potash Mine and entailed the collapse of about 3200 pillars in the depth range 850–900 m.

Similarly, the 1995 Solvay Trona Mine, Wyoming, event, with a magnitude of 5.1, involved the collapse of pillars at a depth of 490 m over an area of about 1 km by 2 km (Pechmann *et al.*, 1995); the lateral extent of the mine is somewhat greater than 4 km. In both the 1995 Solvay and 1989 Volkershausen earthquakes surface subsidence and waveform modeling indicated a substantial implosive component to the seismic source (Bennett *et al.*, 1994).

These two examples illustrate the importance of mining method (room and pillar in both cases) in determining the maximum event. The unmined pillars are intended to inhibit stope collapse and the attendant seismicity. If one pillar fails, however, many others can fail in a cascade and the result is an exceptionally large earthquake. In contrast, if pillars are not left, stope collapse and seismicity, localized near the advancing face, occur steadily. Thus, the rate of earthquakes is higher but maximum magnitudes are smaller (McGarr and Wiebols, 1977).

3.1.4 Seismicity Caused by Quarrying or Surface Mining

Pomeroy *et al.* (1976) associated an earthquake sequence in 1974, including a mainshock of magnitude 3.3, with open-pit quarrying operations near Wappingers Falls, New York. The mainshock and aftershocks show very shallow hypocenters (0.5–1.5 km deep) with thrusting mechanisms, directly beneath the quarry. The quarry, which has a long dimension of about 1 km, has been excavated since the early 1900s to a depth of 50 m, providing a total stress change, albeit distributed over many decades, of 1.5 MPa near the surface. Studies of stress direction and magnitude (Sbar and Sykes, 1973) have shown southern New York to be a region of high horizontal compression. In such an environment, the removal of surface material decreases normal stress and increases shear stress on an underlying thrust fault so as to bring it closer to failure.

Pumping operations to prevent quarry flooding can have two opposing effects regarding triggered seismicity. First, these operations lower the water table, reduce the pore pressure and, thus, strengthen the fault and suppress earthquakes. Second, the removal of water reduces the effective overburden load on any subjacent fault thereby weakening the fault and encouraging seismicity. These two effects are sufficiently complex that it is difficult to predict, without substantial additional information, which will dominate. In the case of Wappingers Falls, it appears that dewatering was of little consequence whereas in the following example, fault strengthening due to dewatering predominated until the pumping ceased.

The 1992–1997 sequence of earthquakes centered in the Cacoosing Valley near Reading, PA, originated on a well-identified shallow fault located directly below a quarry and appears to have been triggered by it (Seeber *et al.*, 1998). The damaging January 1994 $M_w = 4.3$ mainshock ruptured an

oblique-reverse fault in the upper 2 km of the crust. The excavation of an 800 m-wide quarry centered directly above this fault presumably brought the fault closer to failure due to the removal of substantial overburden. This unloading effect, however, had started several decades earlier and had ceased in December 1992, 5 months before the onset of seismicity. Evidently, the unloading effect of the quarry operations was offset by a near simultaneous reduction in pore pressure in the seismogenic zone as the quarry was dewatered to allow production [Eq. (1)]. After the quarry operations ceased, however, the original water table was rapidly restored. Pore pressure on the fault 0.5–1 km below the quarry probably rose almost as fast because permeability of the subjacent Cambrian–Ordovician carbonates is high. The strengthening effect of the lowered pore pressure disappeared leaving the effect of the unloading unmitigated and bringing the fault to failure. Seismicity started in May 1992, and included a damaging $M = 4.3$ event.

Other examples of earthquakes triggered by surface unloading are from the Belchatow region in Poland, where events up to magnitude 4.6 have been related to open-pit coal mining (Gibowicz *et al.*, 1981). The excavation in this case was 1 km by 2 km in area and about 100 m deep.

Finally, at the Lompoc diatomite mine, California, surface mining caused at least four events, with magnitudes up to 2.5, between 1981 and 1995 (Yerkes *et al.*, 1983; Sylvester and Heinemann, 1996); the long dimension of this mining operation is about 1000 m. These Lompoc events differ in several respects from their counterparts in stable continental region settings. First, coastal California is an active tectonic setting. Second, the events at Lompoc produced very distinctive fault scarps on the quarry floor (e.g., Sylvester and Heinemann, 1996), whereas surface faulting was not found at Cacoosing or Wappingers Falls.

3.1.5 Pumping and Flooding in Mines and Quarries

Wetmiller *et al.* (1993) outlined the seismicity history of the Falconbridge, Canada, Mine that was closed in 1984 and then allowed to flood in late 1990. The strong correlation reported between the renewed seismicity and the flooding constitutes quite a credible argument that increasing crustal pore pressure tends to stimulate earthquakes, presumably by reducing the effective normal stress [Eq. (1)].

The Cacoosing Valley sequence, just described, is a shallower example of this. The quarry operations were the essential cause of the seismicity but this only occurred after the quarry was abandoned and the attendant flooding restored the pore pressure in the seismogenic zone to its ambient hydrostatic state.

Finally, pumping to prevent flooding in the deep mines of the South African gold fields has strengthened the surrounding crust by drastically reducing the pore pressure from its ambient hydrostatic state (e.g., McGarr *et al.*, 1975). In the ambient

state, the minimum horizontal principal stress is typically about half the vertical overburden stress, the water table is near the surface and pore pressure is close to hydrostatic (McGarr and Gay, 1978; Gay *et al.*, 1984). Based on laboratory evidence, this state of stress and pore pressure is close to failure (Brace and Kohlstedt, 1980). The Witwatersrand tremors, described earlier, occur in spite of the strengthening effect of the large decrease in pore pressure because the change in state of stress from the extensive tabular stopes is sufficient to counteract this effect locally.

3.2 Seismicity Caused by Liquid Injection

3.2.1 Rocky Mountain Arsenal Well

One of the earliest and most spectacular examples of seismicity related to fluid injection occurred near Denver, Colorado in the 1960s (Evans, 1966; Healy *et al.*, 1968). Hazardous wastes were being injected under high pressures at a depth of 3.7 km at the Rocky Mountain Arsenal. Soon after injection started, earthquakes began to be felt in the Denver area, a region that previously had experienced little or no earthquake activity. The seismicity was initially concentrated near the bottom of the injection well, but eventually spread along a linear zone for about 8.7 km. The fault plane solutions for the largest events indicated normal faulting. Of particular interest, however, is that the largest earthquake, of magnitude 4.85 (Herrmann *et al.*, 1981) occurred more than a year after injection had ceased. The injection pressures were of the order of 10 MPa above the initial formation pressure of 27 MPa. Hsieh and Bredehoft (1981) showed that increases in fluid pressure of only 3.2 MPa were sufficient to stimulate activity on favorably oriented faults.

3.2.2 Ashtabula, Ohio

Liquid waste was injected into the 1.8 km deep basal Paleozoic formation of the Appalachian Plateau near Ashtabula Ohio. A magnitude 3.6 mainshock occurred in 1987 a year after the onset of injection and more than 30 km from any other known earthquake. Accurate aftershock hypocenters showed this event to have ruptured, left-laterally, a vertical west-striking fault just below the Precambrian–Paleozoic unconformity (Nicholson and Wesson, 1990; Seeber and Armbruster, 1993). The sequence started where the fault was closest to the well, i.e., 0.7 km from the injection point, and migrated westward about 2 km. The 35 accurately determined hypocenters all cluster along the fault; none are detected at the injection point. This example shows that preexisting structure can play a key role in the spatial distribution of triggered seismicity.

3.2.3 KTB, Germany

By far the deepest example of seismicity caused by liquid injection occurred when 200 m³ of brine were injected into the 70 m open-hole section at the bottom of the 9.1 km main

borehole of the KTB (German Deep Drilling Program) (Zoback and Harjes, 1997). This experiment resulted in several hundred microearthquakes, close to, but somewhat above, the point of injection. The largest event, which occurred 18 h after the start of injection, had a magnitude of 1.4, whereas, for all the remaining events, the magnitudes were less than zero. These KTB events evidently occurred in response to pore pressure changes of 1 MPa or less (Zoback and Harjes, 1997), which is about 0.01 of the ambient pore pressure. The state of shear stress near the bottom of the borehole was estimated, from an extensive set of measurements, to be about 100 MPa (Brudy *et al.*, 1997), which is close to the predicted failure stress at that depth. The results of this experiment in the tectonically stable region of eastern Bavaria is consistent with other measurements in similar settings showing stress levels close to failure. It also suggests that the high deviatoric stress is not limited to near the surface where most of the measurements are taken, but that it extends through the seismogenic part of the crust.

3.2.4 Control of Seismicity

Following the Denver observations, Raleigh *et al.* (1976) performed a partially controlled experiment in Rangely Colorado where water injection for secondary recovery in an oil field was producing low level seismicity ($m < 3.1$). Injection was in a number of wells with depths of up to 2 km. The formation pressure was of the order of 17 MPa. During the experiment, earthquakes could be turned off and on by varying the pore pressure about a critical value of 26 MPa.

Water injected for solution salt mining in Dale, New York (Fletcher and Sykes, 1977) provides another example of a partially controlled experiment, in this case with lower pressures at shallower depths. Earthquakes of magnitude -1 to 1.4 formed a cluster about 650 m across near the bottom of a 426 m injection well. The earthquake activity ceased abruptly when the top hole pressure dropped below 5 MPa.

3.2.5 Summary of Liquid Injection Effects

Earthquakes associated with liquid injection show the following characteristics. First, the seismicity tends to be triggered along preexisting faults that are hydraulically connected with injection points. The earthquake activity is usually concentrated on the portion of the fault with the least hydraulic resistance from the point of injection. Second, there is also evidence of time dependence in injection-related seismicity. Initially, seismicity tends to be concentrated near the injection point and to respond rapidly to changes in injection pressure or rate. As injection proceeds, the zone of influence increases, the upper limit of earthquake magnitudes increases and the response to input pressures becomes more sluggish and subtle. This response tends to lag changes in injection parameters. Activity close to the injection point usually stops immediately after the injection ceases, whereas farther from the injection well earthquakes may continue for some time afterwards.

An excellent review of many more case histories of seismicity related to liquid injection can be found in Nicholson and Wesson (1990).

3.3 Seismicity at Large Impounded Reservoirs

Over the past six decades, numerous cases of seismicity associated with reservoir impoundment have been reported. We briefly describe three examples of reservoir-related seismicity, chosen to highlight different aspects of this complex phenomenon. Koyna produced the largest earthquake associated with reservoir impoundment and presents a clear example of activity lasting for decades. At Aswan, the seismicity was surprisingly deep. At Nurek, detailed observations show how very minor changes in water level can be sufficient to modify the seismicity.

3.3.1 Koyna

The Koyna, India earthquake of 10 December 1967 is the largest earthquake associated with reservoir loading (Gupta and Rastogi, 1976). The earthquake of magnitude 6.5 occurred at the western edge of the Deccan traps, in a region of low natural seismicity. The mainshock was at a depth of less than 5 km, within 10 km of the dam and involved predominantly strike-slip faulting. The water level in the dam at the time of the mainshock was approximately 75 m and the impounded lake was about 52 km long (Gupta *et al.*, 1969). Seismicity continues at Koyna today and a number of significant events since 1967 have been associated with seasonal changes in the reservoir water level (Gupta, 1985). A magnitude 5.2 event in 1973 occurred when the water level in the reservoir had exceeded its previous maximum by only one meter. The seismicity at Koyna – a “main event” of magnitude 6.5 preceded by at least one year of seismicity and followed by persistent activity for more than 30 years – does not fit the usual mainshock–aftershock pattern for tectonic earthquakes. Clearly, the Koyna reservoir has not simply acted to trigger the release of tectonic stress in a normal earthquake sequence. Instead, the reservoir and its annual cycles in water level, continue to interact with the tectonic stress field in a complex manner and is continuing to trigger earthquakes.

3.3.2 Aswan

Lake Nasser, impounded by the 110 m high Aswan dam on the Nile River, Egypt, is one of the largest artificial lakes in the world. A magnitude 5.3 earthquake in November 1981 occurred 60 km upstream from the dam, directly beneath a large embayment that extends west of the former Nile channel (Kebeasy *et al.*, 1987; Simpson *et al.*, 1990). The earthquake was widely felt in upper Egypt, where there is no evidence of prior seismicity of this magnitude in spite of the long historical record. Aswan reservoir is relatively shallow by world

standards, with water depths of greater than a few tens of meters being confined to the narrow channel of the Nile River. The water level in the embayment where the earthquake occurred is less than 10 m, but the groundwater level in the epicentral area prior to impoundment is known from well data to be more than 100 m below ground level. Simpson *et al.* (1990) suggest that the flooding of the porous Nubian sandstone beneath the embayment created an effective load whose impact greatly exceeded that of the reservoir itself.

The Aswan earthquake and the long sequence of earthquakes that followed are unique among cases of reservoir-triggered earthquakes in terms of the depths to which they extended. The main shock was well recorded by regional stations and the aftershocks were intensely studied by a local telemetered seismic network (Simpson *et al.*, 1990). The mainshock was located at a depth of 18 km. The earthquakes located with the local network showed two distinct clusters of seismicity: one extending from near the surface to 10 km; the other centered about the mainshock depth and extending from 15 to 25 km. The mainshock and many aftershocks were spatially correlated and show the seismicity to be related to the Kalabsha fault, an ancient right-lateral, strike-slip structure which extends west from the Nile channel and controls the topography in the epicentral area.

3.3.3 Nurek

At 315 m, the Nurek dam, on the Vakhsh River, Tadjikistan is the highest dam in the world and is situated in the Tadjik depression, a region of moderately high seismicity. The reservoir filled in stages, with the first major increase in water level to 100 m occurring in 1972. Two earthquakes of magnitude 4.6 and 4.3 occurred beneath the 50 km-long reservoir, immediately after the water level abruptly stopped rising after reaching the 100 m level in November 1972 (Simpson and Negmatullaev, 1981). Long-term monitoring of the regional seismicity for 20 years before construction of the dam clearly shows the activity following impoundment to be anomalous. Detailed monitoring of the postimpoundment seismicity with a local network revealed a close association of the rate of seismicity with minor changes in both the depth of water in the reservoir and changes in the rate of filling (Simpson and Negmatullaev, 1981). Similar effects observed at Lake Mead (Carder, 1970), on the Arizona–Nevada border, were analyzed by Roeloffs (1988).

The second stage of filling the Nurek reservoir, to over 200 m in 1976, was carried out much more smoothly than the first stage of filling in 1972. A strong burst of low magnitude activity accompanied a rapid, but minor fluctuation in water level, when a tunnel was tested part way through the filling cycle. The maximum level of 200 m was reached gradually, however, and no significant earthquakes or increases in activity accompanied the final filling stage. The seismicity at Nurek is especially sensitive to a sudden drop in water level or

a rapid decrease in the filling rate. Simpson and Negmatullaev (1981) showed that water-level changes of a few meters (few $\times 0.01$ MPa) and changes in the rate of filling of as small as 0.5 m day^{-1} can influence the rate of seismicity.

3.3.4 Triggering Mechanisms

The mechanism of earthquake triggering by large reservoirs is more complex than most other types of triggered seismicity. This is partly a consequence of scale – the mass of water impounded in a large reservoir is typically orders of magnitude larger than in an injection project, for example. The area affected is also much larger and can cover extensive changes in geology and fault structure. In addition, reservoir-triggered seismicity can involve a complex interaction between all three of the factors indicated in Figure 2. The weight of the reservoir can influence both shear and normal stress. Pore pressure increases instantly from the compaction of pore space due to the reservoir load and then from the raised water column with a delay due to diffusion. Because of temporal differences in the response to load and pore pressure, Simpson *et al.* (1988) showed that reservoir-triggered seismicity can be divided into two types: a rapid response related to instantaneous elastic response and a delayed response related to fluid diffusion.

Reservoir loading differs from injection- or mining-related seismicity in that the triggering agent (water in the reservoir) is remote from, and in some cases isolated from, the fault zones on which the triggered activity occurs. The pressure change at the bottom of a 100 m deep reservoir is 1 MPa. In a simple elastic medium, only a small fraction of this stress is propagated to hypocentral depths (Gough, 1978; Bell and Nur, 1978).

If the triggering mechanism is an increase in pore pressure from diffusion of water into permeable zones intersecting the reservoir, the influence at depth is also attenuated, and delayed as well. The amount of attenuation depends on rock properties and geometry of the reservoir, but simple elastic models show that stress at depths of a few kilometers can only be about 10% of the surface value (Bell and Nur, 1978). Under these conditions, a 100 m deep reservoir would thus increase the stress at hypocentral depths by, at most, 0.1 MPa. This is considerably lower than the stress changes we have shown to be acting in cases of mining seismicity, but is of the same order as the stress changes in simple elastic modeling for earthquake–earthquake triggering (e.g., Harris, 1998). For such small changes in stress to be sufficient to initiate failure, the pre-existing state of stress needs to be much less than one stress drop away from failure. This condition is statistically possible on a subset of the potentially seismogenic faults. The relatively common occurrence of seismicity triggered by small stress changes would require many such faults, even in areas where natural seismicity is low (Seeber *et al.*, 1996). Alternatively, the stress change may be locally amplified on the affected faults. Simpson and Narasimhan (1990) have

proposed that structural or lithological inhomogeneities can provide one mechanism to produce the necessary stress amplification.

3.4 Hydrocarbon Reservoir Compaction

Seismicity associated with fluid extraction was first recognized in the oil field at Goose Creek, Texas, in 1925 (Yerkes and Castle, 1976). In the meantime, numerous other examples of this phenomenon have been recognized, with the oil field at Wilmington, California producing the most spectacular effects of compaction-caused subsidence, horizontal deformation and attendant earthquakes (Kovach, 1974; Yerkes and Castle, 1976). Yerkes and Castle (1976) demonstrated that differential compaction at depth, due to liquid extraction from the producing formations, could lead to shear failure, including earthquakes.

As reviewed by Segall (1989), the phenomenology of earthquakes associated with hydrocarbon production includes:

1. Seismicity in the immediate environs of a reservoir commences when the pore pressure reduction reaches a level of the order of 10 MPa.
2. The earthquakes tend to occur either immediately above or below the reservoirs and are most prevalent in strata that are especially strong with a tendency toward brittle, rather than ductile, failure.
3. For earthquakes above and below the reservoir, the most common focal mechanisms indicate thrust or reverse faulting; normal faulting mechanisms have been observed for events located in the peripheral region.
4. Earthquakes located in the weaker strata tend to be slow, i.e., the source duration is quite extended compared to that of a typical crustal earthquake of similar magnitude (e.g., Kovach, 1974).

Noteworthy among many examples of seismicity triggered by hydrocarbon extraction are the earthquakes located in the environs of the Rocky Mountain House gas field in Alberta, Canada (Wetmiller, 1986). The substantial reverse slip accumulated on a surface fault at the Buena Vista Hills oil field, in the San Joaquin Valley, California, was aseismic (Kock, 1933; Nason *et al.*, 1968).

Grasso and Wittlinger (1990) described earthquakes triggered by natural gas production in the Pau basin, near Lacq in southwestern France. The gas field, about 10 km in extent with production from depths near 4 km, triggered an exceptionally high level of seismicity for this type of operation, with earthquake magnitudes ranging up to 4.2. These are, so far, the largest events unequivocally associated with reservoir compaction.

Pennington *et al.* (1986) described earthquakes triggered by fluid depressurization in oil and gas fields of south Texas. Earthquakes of $M = 3.9$ in July 1983 (largest) and $M = 3.4$ in March 1984 were located in the Imogene oil field near the town

of Pleasanton and in the Fashing gas field adjacent to the town of the same name, respectively. The Imogene field has a long dimension of about 13.5 km whereas that of the Fashing field is about 7 km (Pennington *et al.*, 1986, Figure 1 of that report).

To understand these effects more quantitatively, Segall (1985, 1989) modeled the hydrocarbon reservoir as a poroelastic medium (Biot, 1941) embedded in an impermeable elastic half-space for purposes of calculating the deformation and stress changes due to fluid extraction (see also Geertsma, 1973) assuming a plane strain geometry. Essentially, hydrocarbon production removes fluid (oil, water, or natural gas) from the reservoir, which responds by contracting. This contraction induces both deformation and stress changes in the strata surrounding the reservoir. The calculated deformation can be compared to geodetic measurements of surface subsidence (e.g., Segall, 1985) and horizontal crustal deformation (Yerkes and Castle, 1976). Similarly, calculated stress changes can be compared to focal mechanisms of nearby earthquakes (e.g., Segall, 1989).

Solutions to the linear poroelastic equations for axisymmetric reservoirs, developed by Segall (1992), were applied to the analysis of subsidence and earthquakes associated with the Lacq gas field by Segall *et al.* (1994). Good agreement between computed vertical displacement and geodetically observed subsidence confirmed that the linear model was realistic. Interestingly, the stress changes, computed from the same model, indicate that the earthquakes at Lacq (Grasso and Wittlinger, 1990) are occurring in response to changes of about 0.2 MPa, or less.

Generally, the deformational response of the crust, at least at the surface, to fluid extraction from oil or gas reservoirs seems to be reasonably well understood judging from the success of linear poroelastic models for replicating geodetically measured subsidence (e.g., Segall, 1985; Segall *et al.*, 1994). Such models have, so far, proved to be of more limited use in understanding earthquakes stimulated by oil or gas extraction, partly because the seismic response to hydrocarbon production is highly variable from field to field (e.g., Doser *et al.*, 1992). Evidently, the mechanical characteristics of the strata above and below the producing formation play substantial roles in the seismic response (Volant, 1993). In fact, no seismicity is observed in the vast majority of producing gas and oil fields. Even in cases for which a rich seismic sequence is associated with hydrocarbon production, as in the Lacq field (e.g., Grasso and Feignier, 1990), this seismicity accounts for only a small fraction of the crustal deformation measured geodetically.

3.4.1 Large Midcrustal Earthquakes Beneath Oil and Gas Fields

3.4.1.1 California Earthquakes

Although the 1983 Coalinga earthquake occurred beneath a major producing oil field, the likelihood of a connection

between oil production and the earthquake sequence was considered by most seismologists to be quite small, primarily because of the eight vertical kilometers separating the hypocenter from the producing formations (Segall, 1985) and because of the relatively high level of natural seismicity in the area. But the ensuing occurrence of large earthquakes directly beneath two other oil fields from which exceptional amounts of liquid had been extracted, i.e., the 1985 $M=6.1$ Kettleman North Dome and the 1987 $M=6$ Whittier Narrows earthquakes, generated renewed interest in a possible link between oil production and large, midcrustal earthquakes. McGarr (1991) noted that the dimensions of the oil fields, 13 km for Coalinga, 23 km for Kettleman North Dome, and 6 km for the Montebello field above the Whittier Narrows earthquake, are similar to the dimensions of the respective aftershock sequences.

Of particular interest, though, is that the ratios of net liquid production to total seismic moment are nearly the same for all three events. This last observation suggests the following mechanism relating the earthquakes to oil production. Because oil production results in a net removal of mass from an oil field (extracted oil + water – injected liquid), the isostatic response of the crust to this mass removal is to thicken so as to restore the vertical force equilibrium. This crustal thickening can be accommodated by thrust faulting, in a region of compressional tectonics, and so the total seismic deformation can be related to the corresponding liquid production (McGarr, 1991). As presented by McGarr (1991, see Table 1 of that report), the agreement between the seismic deformation and expectations based on liquid production is quite good. This proposed mechanism remains speculative, nonetheless, for a number of reasons including several discussed in the next example.

3.4.1.2 Gazli

The region surrounding the desert town of Gazli, Uzbekistan, was relatively aseismic until April 1976, when a $M=7$ earthquake occurred. This was followed by two more $M=7$ events, one in May 1976 and another eight years later in March 1984, together with a rich sequence of small events spanning an arcuate region, elongated in the east–west direction (Simpson and Leith, 1985).

Simpson and Leith (1985) noted the possibility that this impressive earthquake sequence was related to the enormous natural gas field immediately to the south. They remarked that (1) this area had no history of large seismic events before the gas extraction operations, suggesting that this sequence of $M=7$ events is anomalous and (2) the persistent high level of seismicity, including three $M=7$ events does not form a typical foreshock–mainshock–aftershock pattern. Of particular interest, the arcuate region of seismicity is approximately the same size as the gas field, whose long dimension is about 49 km in the east–west direction (Bossu, 1996).

After numerous recent investigations near Gazli (e.g., Grasso, 1992, 1993; Amorese *et al.*, 1995; Bossu *et al.*, 1996; Bossu and Grasso, 1996; and summarized most recently by Bossu, 1996) more information with which to decide whether the gas field and the earthquakes are related is now available than when Simpson and Leith wrote their report. With depths of 20, 13, and 15 km, in order of their occurrence (Bossu *et al.*, 1996), and with focal mechanisms that largely involve thrust faulting on fault planes that do not extend to the surface (Bossu, 1996), the three Gazli $M=7$ events are similar to their counterparts beneath the three California oil fields, of the preceding example. If these large-magnitude earthquakes, located at midcrustal depths, are connected to gas production, limited to depths only slightly greater than 1 km, the responsible mechanism is likely to involve the entire upper brittle crust. Might crustal thickening in response to an isostatic imbalance due to production, proposed

for the three California earthquakes, also apply to the events at Gazli?

From some of the gas field production information presented by Bossu (1996), one could argue either way. On the one hand, Grasso (1992) noted that either the mass of gas produced from the reservoirs at Gazli or the mass of water infiltrating the reservoirs as gas is produced suffices to account for an appreciable fraction of the seismic deformation (McGarr, 1991). On the other hand, Bossu (1996) pointed out that these two contributions to the crustal load, extracted gas and infiltrated water, tend to cancel one another; in fact, the mass of the infiltrated water apparently predominates. In this way Bossu (1996) concluded that the earthquake sequence and gas production are probably unrelated to the restoration of isostatic equilibrium because gas production added, rather than subtracted, mass to the local crustal load. According to Bossu (1996) about 300 million metric tons of gas was

FIGURE 3 Maximum magnitude as a function of scale for 20 case histories. The scale is the maximum dimension of the causative activity as explained in the text. The letter identifications for the case histories, in the same order as they appear in the text, are: underground mining: SAF, deep gold mines in South Africa; URL, Underground Research Laboratory; SOL, Solvay Trona; quarry and surface mining: WPF, Wappingers Falls; CVP, Cacoosing Valley; BEL, Belchatow; LOM, Lompoc Diatomite; Liquid injection: RMA, Rocky Mountain Arsenal; ASH, Ashtabula; DNY, Dale NY; KTB, KTB, Germany; reservoir impoundment: KOY, Koyna; NUR, Nurek; Oil/gas production: LAQ, Lacq; PLT, Pleasanton TX; FTX, Fashing TX; COA, Coalinga; KHC, Kettleman North Dome; WNC, Whittier Narrows; GAZ, Gazli.

extracted whereas, about 1200 million metric tons of water infiltrated the gas field.

4. Effects of Scale

An important question regarding induced or triggered seismicity involves the maximum magnitude earthquake that might result from a particular human activity. For instance, if a dam that impounds a large reservoir is built, what is the maximum credible earthquake that might result?

As described in previous sections, there are several measures of any particular activity that can be related to the total seismic deformation, which, in turn, can be used to estimate the maximum credible earthquake for that activity. Examples include volumes of slope collapse in deep mines (e.g., McGarr and Wiebols, 1977) and the crustal load changes associated with large-scale oil and gas production mentioned in the previous section.

Here, however, we use the maximum dimension of an activity as a simple metric that can be compared to the corresponding maximum magnitude. As described for the case histories reviewed in previous sections, it was straightforward to estimate appropriate maximum dimensions for 20 of them, and Figure 3 shows that the long dimension of an activity correlates fairly well with the corresponding maximum magnitude.

Interestingly, the upper-bound envelope to the data of Figure 3 has an average slope close to 2, suggesting that for an activity of a given size there is an upper limit to the magnitude of the corresponding maximum credible earthquake. For instance, if an activity were 10 km in extent the maximum credible earthquake would presumably have a magnitude near 6. It is important to note, however, that no seismicity is recorded in many instances where human activities affect the stress over large areas, such as below many impounded reservoirs.

5. Conclusions

The case histories reviewed here help to support the following conclusions.

1. The seismogenic continental crust is in a state of stress close to failure, whether the tectonic setting is active or inactive. Because of this, perturbations of the state of stress toward failure [Eq. (1)], even as small as 0.01 MPa, may trigger seismicity. One implication of this is that, for a given activity, triggered earthquakes are as likely in stable as in active tectonic settings, but within stable regions such events are more obvious because the background seismicity is comparatively low.

2. Among the case histories of induced and triggered seismicity reviewed here, perhaps the only examples of induced seismicity (requiring stress perturbations of the order of the ambient deviatoric stress) are from underground mining. This is because pumping operations to prevent flooding strengthen the rock mass by reducing the pore pressure. Extensive mine excavations, especially at depths of several kilometers, amplify the ambient stresses substantially so as to bring the strengthened rock mass back to the point of failure in localized regions. All of the other case histories seem to involve triggered earthquakes inasmuch as the stress perturbations promoting fault slip are tiny compared to the ambient stress level and, in most cases, are much smaller than a typical earthquake stress drop.
3. The size of an activity that perturbs the crustal state of stress appears to be a good predictor of the maximum credible earthquake for that operation. This is evidently the case for all types of induced and triggered earthquake sequences reviewed here including those due to mining, quarries, liquid injection, large reservoir impoundment, and oil and gas exploitation. It is important to note, however, that many large-scale activities result in little or no recorded seismicity.

Acknowledgments

We thank Trudy Closson and Anne Miller for editorial assistance and Joe Fletcher and Anne Miller for graphics support. R.A. Harris, J.B. Fletcher, and S. Gibowicz provided insightful reviews of this manuscript. Encouragement by H. Kanamori and W.H.K. Lee is gratefully acknowledged. Global Seismicity: 1900–1999

E.R. Engdahl and A. Villaseñor
University of Colorado, Boulder, USA

1. Introduction

The goal of this chapter is to produce a comprehensive and self-consistent catalog of global seismicity spanning the 20th century and with uniformly computer-determined hypocenters whenever possible. Seismicity data spanning long periods of time are essential for a thorough understanding of earthquake phenomena. Seismic activity is nonuniform over time, and the rate of seismic moment release exhibits large temporal variations. Since the average recurrence interval for great earthquakes along any particular plate boundary is on the order of several decades, with longer intervals in regions away from plate boundaries, at best only one seismic cycle has been recorded by the modern global networks, and only the last three decades of that cycle have been intensively studied. Creation of a digital catalog for the century will support and advance comprehensive seismic hazard analyses, as well as studies of global and regional seismotectonics, the seismic cycle, the rupture zones of large earthquakes, the spatial-temporal pattern of seismic moment release along seismic zones or faults, and the repeat time of large damaging earthquakes.

We approach the problem of assembling this centennial catalog by first combining existing global catalogs of earthquake locations and magnitudes into a single catalog. Second, we assign a single magnitude to each event depending on availability. For shallow earthquakes we preferably use the moment magnitude M_w or the surface-wave magnitude M_S . For earthquakes deeper than 60 km we use the moment magnitude M_w , or the body-wave magnitude m_B (broadband) or m_b (short period). Third, we use these assigned magnitudes to determine the magnitude completeness thresholds of the database and to assign magnitude cut-off values as a function of time.

Finally, using a modern Earth model (ak135) and location algorithm (Engdahl *et al.*, 1998), we relocate all events which are within the magnitude cut-off thresholds of the catalog and for which there are digital phase arrival-time data.

2. Seismicity Catalogs

Excellent primary and secondary sources of catalog information about earthquake hypocenters and magnitudes can be found in the archival systems of the International Seismological Centre (ISC) and the US Geological Survey's National Earthquake Information Center (NEIC). These systems are multi-catalog earthquake databases of source parameters, available in computer-readable format, that are either directly determined by the ISC and NEIC or derived from published papers and institutional contributions.

The most valuable catalog included in these databases for the historical period (before 1964; Lee *et al.*, 1988) is the one derived from Gutenberg and Richter's book "Seismicity of the Earth" (Gutenberg and Richter, 1954), which provides hypocenters and magnitudes for most of the larger earthquakes occurring between 1904 and 1952. Before 1904 the main source of hypocenters and magnitudes is Abe and Noguchi (1983a,b). Other catalogs of large earthquakes, such as Abe (1981, 1984), Abe and Noguchi (1983a,b), Båth and Duda (1979), Geller and Kanamori (1977), Pacheco and Sykes (1992), Rothé (1969), and Utsu (1979, 1982a,b), are used mainly as sources of magnitude information. All these catalogs (listed in Appendix 3) are combined into a single catalog by using a hierarchical scheme to integrate the hypocenters for matched events between catalogs and to carry along the associated magnitude estimates. In the end, all hypocenter and magnitude entries in these catalogs are accounted for.

3. Seismic Phase Bulletins

Bulletins differ from catalogs in that they contain reported arrival times for P , S and additional seismic phases for each earthquake, which are used to determine a hypocenter for that event when enough consistent phase data are available. A historical account of the international organizations involved in the collection of phase arrival data and global teleseismic

earthquake location can be found in Chapter 2 by Adams. The primary sources of historical phase data are the bulletins of the International Seismological Summary (ISS) and their predecessors. Unfortunately, bulletins for the historical period are mainly preserved in printed form and are not in a computer-ready, digital format. Recently, a project to relocate all instrumentally recorded earthquakes during the period 1900–1963 was initiated (Villaseñor *et al.*, 1997). In this project the printed bulletins are being converted into digital form by scanning the bulletin pages and applying an optical character recognition procedure. We also have obtained a data tape of hand-entered observations from the ISC that contains almost all of the arrival time data for earthquakes reported by the ISS between 1918 and 1942.

From 1953 to 1963 the ISS only processed events with magnitudes greater than or equal to 6. For this period the bulletins of the Bureau Central International de Séismologie (BCIS) fill in the gaps, but the BCIS phase data have not yet been converted into a digital format and hence were not used in this study.

For the modern period (1964–1999) instrumental phase data for moderate-to-large earthquakes worldwide are already available in digital form from both the ISC and the NEIC. Data from all these sources are integrated and converted into the ISC 96-byte data format adopted for the centennial phase arrival-time database. (Note: please see CENT.DAT on the Handbook CD, under the directory \41Engdahl.)

4. Earth Models and Earthquake Location

Although earthquakes have been instrumentally recorded for more than 100 years, source parameters (locations, magnitudes, and focal mechanisms) for events that occurred before the full implementation of the World-Wide Standardized Seismograph Network (WWSSN) are in general poorly known. In most cases, this is the result of inherent limitations in the station distribution, timing, or low magnification of the instruments. However, many locations for pre-1964 earthquakes are poorly constrained because electronic computers and adequate Earth models were not available at the time the earthquakes occurred and the locations were produced.

In the first part of the century travel-time tables for seismic phases, empirically derived from the historical data, were rudimentary at best. The earliest of these, the Zöppritz–Turner tables (used by the ISS from 1913 to 1929) were inaccurate and incomplete, and valid only for shallow-focus earthquakes. Deep earthquakes had to be accounted for with *ad hoc* corrections. This situation greatly improved with the introduction of the Jeffreys–Bullen (J-B) tables (Jeffreys and Bullen, 1940) which provided a complete, remarkably accurate representation of *P*, *S*, and other later-arriving phases. These tables are

still used by the ISC (the successor agency of the ISS) and the NEIC for routine earthquake location.

Earthquake location procedures during the historical period suffered from the lack of electronic computers to implement them. For example, new earthquakes reported to the ISS were commonly assigned epicenters coincident with those determined for previously reported events in the same region. A new epicenter was only adopted if the phase data appeared significantly incompatible with any preexisting locations. The existence of deep earthquakes was discovered by H.H. Turner in the late 1920s during the production of the ISS bulletins (this discovery was also done, almost simultaneously, by K. Wadati). However, depths for approximately 75% of the earthquakes listed in the ISS bulletins were simply reported as shallow (surface focus). A so-called “abnormal” focal depth was calculated only if the phase data were clearly incompatible with a shallow-focus solution. Thus, constraints on the focal depths of many ISS hypocenters were limited.

In an effort to remedy this situation, Villaseñor *et al.* (1997) are extending the current global catalog of computer-determined hypocenters by producing a comprehensive catalog of all globally detected earthquakes during the historical period with locations determined in a uniform fashion. Relocation of historical earthquakes is accomplished by using a new algorithm for teleseismic location (Engdahl *et al.*, 1998). This algorithm, hereafter referred to as EHB, uses travel-time tables derived from an improved Earth model and incorporates *P*, *S*, and other later-arriving phases in the location procedure. The Earth model used is ak135 (Kennett *et al.*, 1995), a derivation of the iasp91 model (Kennett and Engdahl, 1991). Because most seismic stations are in continental areas, the ak135 model was developed with an average continental crust and upper mantle. The most significant differences between the travel times predicted by these models and the older J-B tables are for upper mantle and core phases. The ak135 model more accurately predicts the observed travel times of later-arriving phases, and is in better agreement with *S*-wave data than the J-B tables.

Corrections for lateral variations from the average crust and upper mantle velocities and ellipticity have also been incorporated. The location procedure uses arrival times for the first arriving *P* and *S* phases, core phases (*PKP*) and depth phases (*pP*, *pwP*, and *sP*). By far the most significant improvements provided by the EHB algorithm are in depth determination, through the inclusion of the teleseismic depth phases (with free-surface and sea-bottom bounce points) *pP*, *pwP*, and *sP*. The ISS bulletins reported depth phases, primarily *pP*, but they were not fully used by the ISS to calculate the hypocenter. These phases, reidentified using a new statistical procedure (Engdahl *et al.*, 1998), are now used to minimize mislocation errors introduced by lateral heterogeneity and to provide powerful constraints on focal depth.

The EHB method has already been successfully applied to earthquakes reported by the ISC and NEIC during the modern

period, providing a uniform database of well-constrained, significantly improved hypocenters. The application of this method to historical earthquakes will also result in a comprehensive and homogeneous digital earthquake catalog for the entire century. However, it is important to point out that the EHB procedure cannot entirely account for the effects of the Earth's lateral heterogeneity on teleseismic earthquake location. Most deeper-than-normal earthquakes occur in subduction zones where aspherical variations in seismic wave velocities are large (i.e., on the order of 5–10%). Such lateral variations in seismic velocity, the uneven spatial distribution of seismological stations, and the specific choice of seismic data used to determine the earthquake hypocenter can easily combine to produce bias in teleseismic earthquake locations of up to several tens of kilometers (Engdahl *et al.*, 1998). The most accurate earthquake locations are best determined using a regional velocity model with phase arrival times from a dense local network, which may differ significantly (especially in focal depth) from the corresponding teleseismic locations. Similarly, for historical earthquakes (especially before the 1930s), locations obtained from macroseismic or geological data (e.g., surface rupture) can be more accurate than teleseismic locations computed using arrival-time data alone.

5. Seismic Station Information

Creation of a comprehensive digital earthquake catalog also requires a comprehensive global seismic station catalog. The ISC and NEIC maintain listings of seismograph station codes and coordinates for stations distributed worldwide (Presgrave *et al.*, 1985). These listings are an invaluable resource to investigators using cataloged earthquake data, representing the only nearly complete listing of station locations, codes, and dates of operation. We have been assisting NEIC in maintaining and updating this listing, particularly for stations operating prior to the installation of the WWSSN, by examining a variety of alternative sources of historical station information. This effort has resulted in establishing consistent station codes for stations having no prior code assigned, defining date ranges over which station codes and coordinates are available, and compiling lists of alternate spellings for listed stations. (Note: please see CENT.STN on the Handbook CD, under the directory \41Engdahl.)

6. Earthquake Magnitudes and Catalog Completeness

Construction of the earthquake hypocenter catalog must include magnitude information. The ISS bulletins do not list earthquake magnitudes, and other organizations did not start reporting magnitudes until the early 1950s. The main source for magnitudes of historical earthquakes is Gutenberg and Richter (1954) which reports magnitudes for approximately 13% of the

earthquakes listed by the ISS and occurring before 1952. Gutenberg and Richter never published the details of the method used to compute magnitudes in “Seismicity of the Earth” (hereafter referred to as M_{GR}) although their relationship with other magnitude scales has been intensively investigated (Geller and Kanamori, 1977; Abe, 1981). For the historical period other commonly reported magnitudes are M_S (surface-wave magnitude as defined by Gutenberg, 1945) and m_B (body-wave magnitude for periods of 5–10 sec as defined in Gutenberg and Richter, 1956). (See Chapter 44 by Utsu for a comparison of magnitude scales.)

For recent earthquakes the main sources of magnitude information are the bulletins of the ISC and the NEIC Preliminary Determination of Epicenters (PDE). The most commonly reported magnitudes in this period for teleseismically recorded earthquakes are M_S (determined using the Prague formula; Vaněk *et al.*, 1962) and m_b (body-wave magnitude for periods around 1 sec as defined by Gutenberg and Richter, 1956). However, from 1964 to 1976 M_S was not systematically reported by the ISC, and to compensate for this we included in the catalog, reliable single station magnitude estimates, such as those reported by Pasadena and Berkeley (California), and Palisades (New York).

When available, moment magnitude (M_w) estimates based on the scalar seismic moment M_0 are preferred (Kanamori, 1977; Hanks and Kanamori, 1979). These values of M_0 are frequently determined with modern methods that use body and/or surface wave waveforms (e.g., Dziewonski *et al.*, 1980; Sipkin, 1982). Reliable estimates of M_w are generally available from the Harvard CMT catalog for most events with M_S larger than about 5.4 during the period 1976–1999. Pacheco and Sykes (1992) report scalar seismic moments for large, shallow events during 1900–1980, and Huang *et al.* (1994, 1997) for large, deep events during 1962–1976.

Combining magnitudes from different types and sources into a single catalog requires some understanding of the relationships between the different magnitude scales. There is an overwhelmingly large set of literature devoted to this subject (for a review see Båth, 1981) but our goal is to produce a set of simple rules for obtaining a single magnitude for each event that results in an earthquake catalog which is representative of the rate of earthquake occurrence for the century at or above specified magnitude thresholds in time. The rules we have used are the following: if M_0 is available the preferred magnitude is M_w ; for earthquakes with focal depth $h \leq 60$ km if M_0 is not available then M_S , m_B , or m_b is selected, in this order of preference; for events with $h > 60$ km if M_0 is not available then m_B or m_b is selected, in this order of preference.

Because of the different magnitude scales used, the magnitudes in the resulting catalog are very heterogeneous. In order to evaluate the completeness of the catalog and to establish a cut-off magnitude and select the earthquakes above that cut-off, all magnitudes must be corrected and reduced to a common reference magnitude scale. It is worth noting that

FIGURE 1 Comparison between magnitudes reported by different catalogs relative to surface wave magnitudes (M_S) reported in Abe's catalog (Abe, 1981, 1984; Abe and Noguchi, 1983a,b). The bin width for all histograms is 0.1 magnitude units, and the number of events in each bin is shown as a percentage of the total number of events. N, total number of events; Avg, average residual; Std, standard deviation of the residuals. Catalogs compared: (a) Pacheco and Sykes (1992); (b) Gutenberg and Richter (1954); (c) Båth and Duda (1979); (d) Rothé (1969); (e) Pasadena single-station magnitude for events before 1960; (f) Pasadena magnitudes after 1959.

these corrections are used exclusively to calculate the catalog completeness (as a whole and as a function of time) and to determine which earthquakes are included in the catalog. The magnitudes listed in the catalog are the uncorrected values from the original sources. We have chosen M_S as the reference magnitude scale for the catalog, and investigated its relationship with other magnitude scales.

Moment magnitude M_w agrees very well with M_S for shallow earthquakes larger than a magnitude of ~ 6.5 , but for smaller earthquakes M_w is larger than M_S . Ekström and Dziewonski (1988) introduced an empirical moment magnitude relationship which, for each value of M_0 (or M_w), provides a magnitude that approximates the global average of M_S for that scalar moment. We use this empirical magnitude for the purpose of event selection and to obtain frequency–magnitude relationships. For deeper earthquakes the relationship of reported magnitudes to M_S is problematic and, lacking a well-determined empirical relationship, we assume it to be equivalent to M_w , m_B , and m_b (in order of preference).

Figure 1a shows the distribution of magnitude differences between M_w from Pacheco and Sykes (1992) and M_S from Abe (1981) for events common to both catalogs. These events have magnitudes greater than 7.0 and the agreement between both magnitudes is very good (the residuals are small and normally distributed with an average value close to zero). Figure 1b shows the comparison between M_{GR} (Gutenberg and Richter, 1954) and M_S (Abe, 1981). Values of M_{GR} are systematically larger than M_S by 0.2 magnitude units on average, and in this case the magnitude residuals are not normally distributed. Abe (1981) analyzed in detail the nature of these differences and found that the distribution of residuals changed with focal depth. Figures 1c and 1d show comparisons between M_S (Abe, 1981) and magnitudes reported by Båth and Duda (1979) and Rothé (1969), respectively. Figures 1e and 1f show differences between M_S (Abe, 1981) and magnitudes reported by Pasadena before and after 1960, respectively. The distribution of magnitude residuals for Pasadena before 1960 is similar to the distribution for M_{GR} , with predominantly positive residuals. However, after 1960 the agreement with M_S (Abe, 1981) is better, and the residual distribution has zero mean. From this analysis we conclude that magnitudes reported by Gutenberg and Richter (1954), Båth and Duda (1979), Rothé (1969), and Pasadena before 1960 must be decreased by 0.2 magnitude units in order to be reduced to the common reference magnitude of the catalog. A similar magnitude bias has been previously found by Pérez and Scholz (1984). The correction applied here is an obvious oversimplification, but a detailed analysis of the causes of the magnitude differences is beyond the scope of this chapter.

For the historical period (1900–1963) a frequency–magnitude plot (Fig. 2a) shows a gentle roll-off in the number of earthquakes per year for $M_S \leq 7.0$ (both for incremental and cumulative number of events). The irregular shape of the curve for the incremental number of events is caused by

FIGURE 2 Frequency–magnitude (Gutenberg and Richter) relations for the centennial catalog. Open circles represent single frequencies (incremental number of earthquakes with magnitudes in $M \pm \delta M/2$) and filled circles represent cumulative frequencies (total number of earthquakes with magnitudes $\geq M$). The width of the magnitude interval δM is 0.1 magnitude units. The single and cumulative frequencies are normalized to events per year, and the magnitudes have been adjusted to M_S (see text): (a) historical seismicity (1900–1963), and (b) recent seismicity (1964–1999).

magnitudes reported with precisions of 0.25 and 0.5 magnitude units. Most missed earthquakes in the $M_S = 6.5$ –7.0 range probably occur during the 1900–1930 period. Hence, to include as many events as possible we have chosen a magnitude of 6.5 as our magnitude cut-off for the historical period.

FIGURE 3 Number of events in the centennial catalog as a function of time for the three magnitude levels specified in the legend: (a) number of events per year; (b) number of events in 10 y intervals. The total number of events in each interval is divided by the interval width to allow direct comparison between the two histograms.

For the modern period (1964–1999) Engdahl *et al.* (1998) have shown that the global catalog is nearly complete to a magnitude of 5.2, where the magnitude is defined as (in descending order of preference) either M_w , M_S , or m_b , depending on availability. A frequency–magnitude plot for the modern period (Fig. 2b) shows that the number of earthquakes per year is consistent with a magnitude threshold of at least M_S 5.5. Hence, with the possible exception of the 1960s when less-reliable magnitudes were available and taking into account

normal yearly fluctuations in the rate of occurrence (Fig. 3a), the centennial catalog seems to be complete to at least M_S 6.5 during the period 1930–1963 and M_S 5.5 during the period 1964–1999, and complete to M_S 7.0 for the entire century.

If our magnitude assumptions are valid, then the rate of earthquake occurrence at any given magnitude threshold should be constant provided that the global rates of seismicity are assumed constant on a timescale of decades (Pacheco and Sykes, 1992) and the catalog is complete at that threshold.

TABLE 1 List of Earthquakes (Magnitude ≥ 7) for 1900–1999.

1999	12	11	18:03 39.0	15.76	119.76	44	7.3	Mw	EHB	HRV	

Explanations:

- (1) Earthquake origin time is given in UTC by: Year, Month (M), Day (d), Hour (h), Minute (min), and Second (sec).
- (2) Earthquake hypocenter is given by: Latitude (Lat.) in degrees (positive for northern hemisphere, and negative for southern hemisphere); Longitude (Long.) in degrees (positive for eastern hemisphere, and negative for western hemisphere); and Focal Depth (Dep.) in kilometers.
- (3) Preferred Magnitude is given by: Magnitude (Mag.) and Magnitude Scale (sc).

Moment magnitude (Mw): Value is computed from the scalar moment (Mo). Mw is related to the scalar moment by the formula $Mw = 2/3 \log Mo - 10.7$ (Hanks and Kanamori, 1979).

Surface-wave magnitude (Ms): Value is computed by ISC/NEIC for earthquakes at depths generally less than 50 km (NEIC) or 60 km (ISC) based on the maximum ground amplitude of surface waves with periods between 18 and 22 seconds that are recorded at distances between 20 and 160 degrees.

Broad-band body-wave magnitude (mB): Value is computed as defined by Gutenberg and Richter (1956) based on the maximum ground amplitude of seismic body-waves with periods of 5-10 s that are recorded at distances greater than or equal to 5 degrees.

Body-wave magnitude (mb): Value is computed by ISC/NEIC based on the maximum ground amplitude of seismic body-waves with periods of 0.1-3 s that are recorded at distances greater than or equal to 5 degrees.

Japan Meteorological Agency magnitude (Mj): Value is computed using either maximum ground displacement or maximum ground velocity.

Unknown magnitudes (UK): The computational method was unknown and could not be determined from published sources. Examples of unknown magnitudes are the ones calculated by Gutenberg and Richter in "Seismicity of the Earth" (MGR).

- (4) Source catalog is given in the "icat" column. EHB = EHB origin time and hypocenter (otherwise from other earthquake catalogs).

- (5) Source for magnitude (Mag) is given in the "mdo" column.

- (6) For some well-known earthquakes, the "Region:Earthquake Name" column gives the geographical region where the earthquake occurred, and a commonly cited name for the earthquake in the literature. "NZ" = New Zealand, "Calif." = California, and "Is." = Island.

- (7) Please see Appendix 3 for further explanations of (4) and (5).

TABLE 2 Frequency–Magnitude Distribution for 1900–1999

Incremental			Cumulative	
$\leq M <$		Events y^{-1}	$M \geq$	Events y^{-1}
5.5	6.0	164 ^a	5.5	264 ^a
6.0	6.5	62 ^a	6.0	100 ^a
6.5	7.0	22	6.5	38
7.0	7.5	12	7.0	16
7.5	8.0	3	7.5	4
8.0	—	0.7	8.0	0.7

^aFor magnitudes smaller than 6.5 the number of events is based on the period 1964–1999.

Figure 3b shows a histogram of the number of events per 10-year period in different magnitude intervals for the entire century. We note a slight increase in the number of earthquakes with magnitudes greater than or equal to 6.5 during the 1940–1960 period. Most of the magnitudes for events less than magnitude 7 during this period were those listed by Gutenberg and Richter (1954), suggesting that many of the M_{GR} magnitudes, even after applying the correction previously described, may remain too high when compared to other magnitudes such as those reported by Abe (1981).

In summary, our full global earthquake database is given in CENT.CAT on the Handbook CD, under the directory \41Engdahl, and a subset of earthquakes with magnitude greater than or equal to 7.0 is given in CENT7.CAT in the same directory. For general reference, essential information from CENT7.CAT is listed in Table 1 with names for some well-known earthquakes. According to our analysis, this list is complete for the 20th century. Frequency–magnitude distributions for the century have been estimated from our database and are presented in Table 2. We believe these distributions to be reasonably representative of the rate of earthquake occurrence during the last century.

7. Discussion

The earthquake locations listed in our catalog for the historical period are of variable quality, as not all of the phase data listed in ISS bulletins have been converted into digital format and we were only able to relocate events during the 1918–1942 and 1956–1999 periods. Hence, hypocentral errors, especially in depth, may remain quite large during the missing years (as well as for many relocated events before 1930). Maps of the distribution of earthquake locations in our catalog are shown in Color Plates 15 and 16.

Magnitude issues, such as the hierarchical selection process, are more contentious, especially for earthquakes less than about magnitude 6.5. Since the seismic moment M_0 is a more stable measurement than M_S we chose to convert the Harvard M_0 (when available) to an empirical M_S using the

relationship derived by Ekström and Dziewonski (1988). This empirical M_S approximates the global average value of M_S observed for that scalar moment and thereby ensures that the assignment of magnitudes for most of the modern period (1976–1999) remains reasonably consistent with reported magnitudes for earlier periods, which are largely M_S . We also confirmed that magnitude estimates listed by Abe (1981, 1984) and by Pacheco and Sykes (1992) for larger events were consistent with Harvard M_w estimates. However, when we made a similar comparison to magnitudes reported by Gutenberg and Richter (1954) and by Båth and Duda (1979), we found that those estimates were consistently about 0.2 magnitude units higher than the Abe (1981, 1984) values. Moreover, it was impossible to match the seismicity rates of the historical period to those of the modern period without making a reduction in the older magnitudes by about 0.2 units. However, final resolution of this problem is presently beyond the scope of this study so that, for example, the apparent higher seismicity rate during the 1940–1960 period (Fig. 3b) will remain problematic.

Our magnitude adjustment and selection process will undoubtedly raise concerns about earthquakes which have been cited in the literature as reputedly higher magnitude than we are able to confirm. However, many of these earthquakes cannot be found in our catalog simply because the selection process put them below the magnitude cut-off of 6.5 for the historical period or 5.5 for the modern period.

Both the location and magnitude issues raised here mean that correcting and updating our catalog will be an ongoing process. Hence, as new versions of the catalog are produced, we will make every effort to have them generally available to the global seismological community via the World Wide Web, CD-ROMs, and technical and general publications.

8. Summary and Conclusions

The goal of this research was to produce a comprehensive digital hypocenter and phase arrival-time database for most globally detected earthquakes during the 20th century, including a complete station list with codes, locations, and dates of operation. For the historical period (1900–1963) we have chosen a magnitude cut-off value of 6.5 although the resulting catalog is complete only to magnitude 7.0. For the recent period (1964–1999) the magnitude cut-off is 5.5, and the catalog is complete at this magnitude threshold.

For the earthquake research community, this database should provide a reliable starting point for a wide range of studies, including (but not limited to) source parameter studies, delineation of rupture zones of large earthquakes from after-shock distributions, further improvements in Earth models, and detailed studies of the seismicity of active regions. The new database may also be of great utility in providing fundamental information for reliable seismic hazard assessment,

especially in developing countries located in active seismic belts whose seismic history is poorly known.

Acknowledgments

We are grateful to the ISC for providing unbound copies of the ISS bulletins and for a magnetic tape of punched card images of these bulletins for the period 1918–1942. We thank Willie Lee, Hiroo Kanamori, Jim Dewey, Ray Willemann, and Javier Pacheco for providing helpful reviews of the manuscript. Figures and maps were created using GMT (Wessel and Smith, 1998). This work was partially supported under NSF grant EAR-9506767.

Appendix 1. Centennial Catalog Format Description

The file CENT.CAT, or CENT7.CAT, may be read by the following FORTRAN read statement:

```
read(1,100) icat, asol, isol, yr, mon, day, hr, min, sec,
& glat, glon, dep, greg, ntel, (mag(k), msc(k), mdo(k), k=1, 8)
100 format(a6, a1, a5, i2, 2i3, 1x, 2i3, f6.2, 1x, 2f8.3, f6.1, 2i4,
& 8(f4.1, 1x, a2, 1x, a5))
```

Variable definitions are:

icat	source catalog EHB = EHB origin time and hypocenter (otherwise from other catalogs)
asol	open azimuth of teleseismic stations ($\Delta > 28^\circ$) used for the period 1900–1963 blank = unknown A = $< 180^\circ$ B = $< 210^\circ$ and $> 180^\circ$ C = $< 240^\circ$ and $> 210^\circ$ D = $< 270^\circ$ and $> 240^\circ$ F = $> 270^\circ$ for the period 1964–1999 blank = $< 180^\circ$ Z = $\geq 180^\circ$
isol	solution type HEQ = origin time and hypocenter fixed DEQ = depth free LEQ = depth fixed by program FEQ = depth fixed by Engdahl based on independent information XEQ = poor solution
other info	M = focal mechanism available
yr	year
mon	month

day	day
hr	origin hour (UTC)
min	origin minute
sec	origin second
glat	geographic latitude (degrees: negative value = south)
glon	geographic longitude (degrees: negative value = west)
dep	focal depth (kilometers)
greg	Flinn–Engdahl geographic region number (Flinn <i>et al.</i> , 1974)
ntel	number of teleseismic observations ($\Delta > 28^\circ$) used in solution
magnitudes (up to 8):	first listed is magnitude adopted for the event
mag	magnitude
msc	scale
mdo	source

Appendix 2. Magnitude Scale (msc) Descriptors

Moment magnitude (M_w): Value is computed from the scalar moment (M_0). M_w is related to the scalar moment by the formula $M_w = 2/3 \log M_0 - 10.7$ (Hanks and Kanamori, 1979).

Surface-wave magnitude (M_S): Value is computed by ISC/NEIC for earthquakes at depths generally less than 50 km (NEIC) or 60 km (ISC) based on the maximum ground amplitude of surface waves with periods between 18 and 22 sec that are recorded at distances between 20 and 160 deg.

Energy magnitude (M_E): Value is computed by NEIC from the seismic radiated energy (E_S) obtained from energy spectral density of broadband P waves using the formula $M_E = 2/3 \log E_S - 2.9$ (Choy and Boatwright, 1995).

Broadband body-wave magnitude (m_B): Value is computed as defined by Gutenberg and Richter (1956) based on the maximum ground amplitude of seismic body waves with periods of 5–10 sec that are recorded at distances greater than or equal to 5 deg.

Body-wave magnitude (m_B): Value is computed by ISC/NEIC based on the maximum ground amplitude of seismic body waves with periods of 0.1–3 sec that are recorded at distances greater than or equal to 5 deg.

Japan Meteorological Agency magnitude (M_J): Value is computed using either maximum ground displacement or maximum ground velocity.

Unknown magnitudes (UK): The computational method was unknown and could not be determined from published sources. Examples of unknown magnitudes are the ones calculated by Gutenberg and Richter (1954) (M_{GR}).

Appendix 3. Source Catalog (icat) and Magnitude Source (mdo) Descriptors

ABE: Catalog of large earthquakes, mostly magnitude 6.8 and larger, 1897–1980, from Abe (1981, 1984) and Abe and Noguchi (1983a,b). The magnitude sources AN1, AN2, ABE1 and ABE2 listed in the mdo column of Table 1 are from this catalog.

B&D: Catalog of large earthquakes, 1897–1977, compiled by Båth and Duda (1979).

BRK: Magnitudes reported by the Seismographic Station, University of California, Berkeley, USA.

BJI: Catalog of hypocenters and magnitudes reported by the State Seismological Bureau, Beijing, China.

G&R: Catalog of hypocenters and magnitudes, 1904–1952 (Gutenberg and Richter, 1954).

ISC: Hypocenters and magnitudes from bulletins prepared by the International Seismological Centre, Newbury, UK, 1964–1998.

ISS: Hypocenters listed in the International Seismological Summary, 1918–1963. The same code is used for hypocenters listed in the British Association for the Advancement of Science bulletins (1913–1917), the predecessor of the ISS.

JMA: Catalog of hypocenters and magnitudes, 1926–present, reported by the Japan Meteorological Agency, Tokyo, Japan.

MOS: Catalog of earthquakes occurring in the former USSR, 1950–1961.

P&S: Complete and uniform catalog of worldwide earthquakes with M_S magnitudes of 7.0 and larger at depths less than or equal to 70 km, 1900–1989 (Pacheco and Sykes, 1992).

PAS: Magnitudes reported by the California Institute of Technology, Pasadena, USA.

NEIC, NEIS and C&GS: Catalogs of earthquakes located by the US Geological Survey's NEIC and its predecessors.

ROTHE: Catalog of worldwide earthquakes with magnitudes of 5.5 or larger, 1953–1965 (Rothé, 1969).

UTSU: Catalog of earthquakes in the Japan region, 1885–1925 (Utsu, 1979, 1982a,b).

Computer readable data files for this Chapter are given on the Handbook CD, under the directory \41Engdahl.

A List of Deadly Earthquakes in the World: 1500–2000

Tokuji Utsu

The University of Tokyo, Tokyo, Japan

A list was compiled containing the earthquakes in the world from 1500 through 2000 in which 50 or more (or *many*) people were reported killed. The data have been collected from various catalogs, research articles, and reports on global and regional earthquakes. They are listed in the Bibliography Section. Many other materials on individual earthquakes have

also been used. Since the materials on historical earthquakes accessible to the compiler are limited, and some materials may contain various kinds of inaccuracies, this list is neither complete nor accurate, especially for the old-time events.

All values in the list (see Table 1, Figs. 1–3 by century, and Color Plate No. 17) are taken from some previously published

TABLE 1 A List of Deadly Earthquakes in the World for 1500–2000. See Text for Explanation

Year	Month/day	h:min	Lat.	Long.	<i>M</i>	Deaths	Remarks
1500	1/04		24.9	103.1	7.0	10000s	China: Yunnan P. [Yiliang EQ] ($I \geq 9$) $M \geq 7.0$
1501	1/19		34.8	110.1	7.0	400	China: Shaanxi P. [Chaoyi EQ] ($I = 9$) $D = 170$
1502	1/18	10:00L	37.2	138.2	6.8	many	Japan: Niigata P. (Naoetsu)
1502	10/17	20:00L	35.7	115.3	6.5	150	China: Henan P. [Pucheng EQ] $D = 50/100 + /$ many
1505	7/06		34.7	69.2		great	Afghanistan: Kabul, Bala, Hicar, Pangan ($I = 9$ –10)
1508	5/29		35.2	25.1	7.1	300	Greece: Ierapetra, Megalokastron (Crete) [T]
1509			13.2	43.6		many	Yemen: Mawza (1509–1510)
1509	9/14		41.0	28.8	7.4	13000	Turkey: Tsurlu, Istanbul ($I = 10$ –11) [T]
1510	6/10		48.8	10.5		many	Germany: Nordlingen $D = 2000?$
1510	9/11	4:00L	34.6	135.6	6.8	many	Japan: Osaka P. [T]
1511	3/26	14:40U	46.2	13.4	6.9	many	Slovenia: Idrija/Italy: Friuli $D = 3T/6T/12T$
1512			46.4	9.0		many	Switzerland ($I = 7$)
1512	10/08		25.0	98.5	6.8	many	China: Yunnan P. [Tengchong EQ] ($I = 9$)
1514	4/16		37.7	21.0	6.5	many	Greece: Zakynthos ($I = 10$)
1514	9/18		25.1	99.1	5.5	many	China: Yunnan P. [Baoshan EQ] Date = 9/18–28
1515	6/17		26.6	100.7	7.8	1000s	China: Yunnan P. [Heqing EQ] ($I = 10$) $D = 100s?$
1515	10/23		25.7	100.2	6.0	100s	China: Yunnan P. [Dali EQ] ($I = 8$)
1518	11/09		37.2	–1.5		many	Spain: Vera (Almeria) ($I = 9$ –11)
1522	9/21		36.5	–2.3		many	Spain: Almeria, Granada ($I = 9$ –11) Date = 9/22?
1522	10/22		38.0	–25.0		5000	Azores: S. Miguel ($I = 10$)
1530	9/01	14:30U	10.7	–64.1		many	Venezuela: Cumana, Paria ($I = 10$) [T]
1531	1/26		39.0	–8.0		30000	Portugal: Lisbon/Spain/Morocco $D =$ many/1T [T]

materials. No new estimation of epicenters and magnitudes has been made. (For revised times, locations, and magnitudes of events since 1900, see Chapter 41 by Engdahl and Villaseñor.) If different values are found in an item among different sources, the one that seems to be most appropriate has been adopted, although an objective assessment of the reliability of data is difficult in many cases. Numbers of deaths for an earthquake from different literature often differ very widely. In such cases, numbers different from the one shown in the column “Deaths” have been included in the column “Remarks” in the form such as D = 850/2T/1000s (2T = 2000, 1000s = thousands). In some cases, casualties are given using the letter C.

Magnitudes shown in the column “*M*” have been taken from various sources. For example, all magnitudes of the earthquakes in Japan are the JMA (Japan Meteorological Agency) magnitudes or equivalents. All magnitudes of the earthquakes in China are taken from recent Chinese works. For most Italian earthquakes, magnitudes given in Boschi *et al.* (2000) have been used. The surface-wave magnitude M_S (or the body-wave magnitude m_B for intermediate-depth earthquakes) and the moment magnitude M_W are given in the column “Remarks.” They are marked with S (or B) and W, respectively. The M_S and m_B values are taken from Abe (1981) and Abe and Noguchi (1983a,b). The M_W values are converted from the seismic moments given in the Harvard University’s CMT catalog for earthquakes in and after 1977. The M_W values before 1977 are taken from various papers.

The column “Remarks” includes the country and place names where the damage seems to be most severe. Place

names represent cities, towns, villages, or, in some cases, provinces, prefectures, and other names of regions according to the sources adopted. Old names are, as a rule, replaced by the present names, such as Istanbul (formerly Constantinople) and Tokyo (formerly Edo). However, some place names not found in the atlas remain as they were. “P.” following a place name means Province or Prefecture. “A.R.” means Autonomous Region in China. “EQ” is an abbreviation for Earthquake.

The maximum seismic intensity (or estimated intensity at the epicenter) based on a twelve-grade intensity scale (the MM scale, MSK scale, or similar scales used in some countries) is indicated when available and if space allows, such as (I = 9).

Earthquakes accompanied by a great fire, surface faulting, a large landslide, and a tsunami are indicated by marks [C], [F], [L], and [T], respectively. [R] indicates the formation of a dammed lake (and the flood due to the subsequent collapse of the dam in most cases). [V] means that the earthquake occurred during the eruption of a volcano.

Acknowledgments

The compiler wishes to thank W.H.K. Lee, S. Miyamura, and an anonymous reviewer for helpful advice, and S.R. Walter of the US Geological Survey for preparing the figures and color plate.

Statistical Features of Seismicity

Tokuji Utsu

The University of Tokyo, Tokyo, Japan

1. Introduction

Statistical studies of earthquake occurrences have frequently been carried out since the early years of seismology. To obtain reliable results from statistical analysis, a sufficient amount of high-quality data is necessary. The data are taken usually from earthquake catalogs, but many of the existing catalogs are inhomogeneous and incomplete. When we use seismicity data, special care must be taken to avoid or correct these defects in the catalogs.

In most statistical studies, earthquakes are represented by point events in a five-dimensional space–time–size continuum. In ordinary earthquake catalogs, the five coordinates are given as longitude and latitude of epicenter, focal depth, origin time, and magnitude. There are many other quantities which characterize an earthquake, fault-plane parameters (or more generally moment tensor components), stress drop, fault rupture length, rupture velocity, etc. Statistical studies involving these quantities are few. This is mainly because the complete data set on these is unavailable especially for small or old earthquakes.

The results of a statistical analysis must be tested for significance. Every method for a significance test is based on certain assumptions. When we use a method, we must remember the underlying assumptions.

It is often the case that we examine two or more data sets and choose the one for which the statistical property in question is most clearly recognized. The effect of such preferential selection of data set must be considered in the significance test. There is no common way of deciding how the significance level must be changed to compensate this effect. Numerical simulation may provide a solution in some cases.

2. Statistical Properties of Earthquake Sequences

2.1 Identification and Classification of Earthquake Sequences

Since the spatial and temporal clustering of earthquakes is the most prominent feature of most earthquake catalogs, we will

first consider the properties of earthquake clusters, such as (foreshock–)mainshock–aftershock sequences and earthquake swarms.

There is no universally accepted exact definition of aftershocks, foreshocks, and earthquake swarms. We must give a working definition when we perform a statistical analysis on them. Figure 1a–d shows plots of occurrence rate versus time for typical earthquake sequences. The successive occurrence of mainshock–aftershock sequences of similar size (Fig. 1d) is also called an earthquake swarm, but it is apparently different from an ordinary swarm (Fig. 1c).

In statistical studies of seismicity, we sometimes use declustered catalogs, which contain only independent events (mainshocks and isolated earthquakes; the largest shock in a swarm is considered as the mainshock). Most algorithms for declustering (i.e., identification of earthquake sequences) use either space–time windows to include clustered events or space–time separations to link clustered events. For declustering or cluster identification algorithms, see Davis and Frohlich (1991a), Molchan and Dmitrieva (1992), and references in these papers. Studies using declustered catalogs or lists of earthquake clusters obtained by declustering are found in Utsu (1972a), Prozorov and Dziewonski (1982), Reasenber (1985), Prozorov (1986), Keilis-Borok and Kossobokov (1990), Frohlich and Davis (1990), Davis and Frohlich (1991a,b), Ogata *et al.* (1995), and many others.

2.2 Aftershocks

2.2.1 Temporal Distribution of Aftershocks

Omori (1894) showed that the frequency of felt aftershocks per day, $n(t)$, following the 1891 Nobi, central Japan, earthquake ($M=8.0$) decreased regularly with time according to the equation

$$n(t) = K(t + c)^{-1} \quad (1)$$

where K and c are constants and t is the time measured from the mainshock. The cumulative number of aftershocks, $N(t)$,

FIGURE 1 Examples of earthquake sequences. Temporal variations in the occurrence frequency per three hours are shown. (a) Mainshock–aftershock sequence; (b) foreshock–mainshock–aftershock sequence; (c) earthquake swarm; (d) successive occurrence of mainshock–aftershock sequences (earthquake swarm of the second kind).

plotted against $\log t$, tends to a straight line with time, because

$$N(t) = \int_0^t n(s) ds = K \ln(t/c + 1) \quad (2)$$

Utsu (1961) plotted the data of $N(t)$ for 44 aftershock sequences against $\log t$, and showed that the slope of cumulative curve tends to decrease with time for most sequences. He reached the conclusion that Eq. (3) fits the data more closely and called it the modified Omori formula

$$n(t) = K(t + c)^{-p} \quad (3)$$

where p is a constant somewhat larger than 1.0 (mostly 1.0–1.5). $N(t)$ for Eq. (3) is given by

$$N(t) = K\{c^{1-p} - (t + c)^{1-p}\}/(p - 1) \quad (p \neq 1) \quad (4)$$

If the origin times t_i ($i = 1, 2, \dots$) are available for all aftershocks of $M \geq M_z$ occurring in a certain period of time, we can compute the maximum likelihood estimates of K , p , and c (Ogata, 1983a). If the data contain the background seismicity of the region, it is recommended to use the equation $n(t) = K(t + c)^{-p} + B$ and estimate the background level B at the same time.

Computer programs for obtaining the maximum likelihood estimates of K , p , c , and B values and their standard errors for a given set of data are available in *IASPEI Software Library* Vol. 6 (Utsu and Ogata, 1997). This package contains the programs for the double sequence (the second sequence starts at $t = t_d$)

$$n(t) = K_1(t + c_1)^{-p_1} + K_2(t + t_d + c_2)^{-p_2} \quad (5)$$

$(K_2 = 0 \text{ for } t < t_d)$

and the triple sequence as well as some other formulas including the Weibull distribution

$$n(t) = K\alpha\beta t^{\beta-1} \exp(-\alpha t^\beta) \quad (6)$$

The stretched exponential function used by Kisslinger (1993) is the same as Eq. (6). Gross and Kisslinger (1994) tried more general equations.

The K value in the modified Omori relation depends strongly on the threshold magnitude M_z . The p value seems to be almost independent of M_z (e.g., Utsu, 1962). This is consistent with the stability of mean magnitude $\bar{M}$ (or b value) during an aftershock sequence (e.g., Lomnitz, 1966). The c value often shows strong dependence on M_z . This is mainly due to the deficiency of data. Small aftershocks occurring shortly after the mainshock tend to be missing due to overlapping of seismograms. One recent example supporting the modified Omori relation and the independence of p on M_z is shown in Figure 2 [see also Utsu *et al.* (1995) and Ogata (1999b)]. Nyffenegger and Frohlich (1998) investigated the factors that influence the maximum likelihood estimate of p value. Wiemer and Katsumata (1999) showed spatial variation of p and b values in the aftershock zones of four earthquakes (see also Utsu, 1962). Kisslinger (1996) presented a comprehensive review on aftershock phenomena.

2.2.2 Spatial Distribution of Aftershocks

It had been known before the introduction of earthquake magnitude that the aftershock epicenters scatter more widely for larger mainshocks. Utsu and Seki (1955) introduced the earthquake magnitude in this problem and obtained a relation $\log S = 1.02M_m - 4.01$, where S is the aftershock area in km^2 for a mainshock of magnitude M_m from the data of 40 mainshock-aftershock sequences in Japan ($6 \leq M_m \leq 8.5$). This equation can be written in a simpler form

$$\log S = M_m - 3.9 \quad (7)$$

If we consider a rectangular aftershock area with length L and width W and simply assume that $W = L/2$, Eq. (8) can be transformed to an equation proposed by Utsu (1961, 1969)

$$\log L = 0.5 M_m - 1.8 \quad (8)$$

Although an aftershock zone roughly corresponds to the fault ruptured during the mainshock, precise studies indicate that

FIGURE 2 Modified Omori curves (top: rate, bottom: cumulative number) fitted to the aftershock sequences of the Hyogoken-Nanbu (Kobe) earthquake of 16 January 1995 (M_w 6.9). Data are taken from the Japan Meteorological Agency catalog. All earthquakes occurring in the rectangular area shown in the inserted map with focal depth less than 40 km are designated as aftershocks. The data and curves corresponding to the four (or two) different threshold magnitudes are shown. Note the independence of p value on the threshold magnitude.

aftershocks are concentrated near the margin of the fault area where the large displacement occurred (e.g., Hartzell and Heaton, 1986; Mendoza and Hartzell, 1988; Takeo, 1988). The relation between surface rupture length and M_m may have different coefficients (e.g., Tocher, 1958; Iida, 1965; Matsuda, 1975; Wells and Coppersmith, 1994), because the surface rupture does not always represent the entire fault rupture responsible for the earthquake.

There are many studies, which relate the size of aftershock zone to the mainshock magnitude. For example, Acharya (1979) obtained similar equations to Eq. (7) for five regions in

the Circum-Pacific zone, but the coefficient of M_m scatters from 0.78 to 1.22. Iio (1986) obtained

$$\log L = 0.43 M_m - 1.7 \quad (9)$$

for smaller earthquakes in Japan ($3.8 \leq M_m \leq 6.2$).

The aftershock zones sometimes show considerable expansion within days to years from the mainshock. For related studies, see Mogi (1968a) and Tajima and Kanamori (1985).

2.2.3 Aftershock Activity

The degree of aftershock activity relative to the mainshock size may be expressed by $\sum_{i=1}^{\infty} E_i/E_m$, where E_m and E_i denote the energy (or moment) of the mainshock and the i th largest aftershock, respectively. Since the energy (or moment) of the largest aftershock, E_1 , is roughly proportional to the total energy (or moment), the aftershock activity is roughly represented by E_1/E_m , which corresponds to the magnitude difference between the mainshock and the largest aftershock

$$D_1 = M_m - M_1 \quad (10)$$

D_1 values for many mainshock–aftershock sequences have been investigated for its regional variation and dependence on M_m . Although $D_1 = 1.2$ is known as Båth's law (Richter, 1958), D_1 actually varies very widely from 0 to 3 or more.

The relation between D_1 and M_m has been studied by Utsu (1961) and several other workers. Utsu (1969) expressed $\tilde{D}_1$ (median of D_1 for mainshock magnitude M_m) as $\tilde{D}_1 = 5.0 - 0.5 M_m$ for $8.0 \geq M_m \geq 6.0$ and $\tilde{D}_1 = 2.0$ for $M_m \leq 6.0$ for shallow earthquakes in Japan. Most other workers gave a smaller average D_1 value for M_m less than about 6.5. For example, average D_1 for $M_m = 6.0$ is 0.67, 1.08, 1.14, and 1.05 according to Papazachos *et al.* (1967), Papazachos (1971), Båth (1977), and Kisslinger and Jones (1991), respectively. The difference between Utsu and most other workers may be caused by the difference in data-acquisition principle. Utsu considered the existence of earthquakes whose aftershocks were too small to be observed. Studies of regional variation of D_1 are found in Mogi (1967), Utsu (1969), Tsapanos (1990), Doser (1990), etc.

The aftershock activity has also been discussed by using the number of aftershocks above a certain magnitude level. For example, Singh and Suárez (1988) expressed the average number N of aftershocks of $m_b \geq 5$ accompanying large thrust earthquakes of moment magnitude M_w along the Circum-Pacific subduction zones. The relation is given by $\log N = M_w - 6.34$. Some systematic deviations from the average seem to depend on the degree of interplate coupling and complexities of the source. See Papazachos (1971), Lamoreaux *et al.* (1983), Yamanaka and Shimazaki (1990), and Davis and Frohlich (1991a) for regional trends.

Deep earthquakes are accompanied by few aftershocks (e.g., Wadati, 1931; Frohlich, 1987). Examples of aftershocks of deep earthquakes and depth variation of aftershock activity have been reported by Solov'ev and Solov'eva (1962), Prozorov and Dziewonski (1982), Pavlis and Hamburger (1991), Wiens *et al.* (1997), among others.

2.3 Foreshocks

Foreshocks are generally infrequent as compared with aftershocks. Foreshock activities are highly variable. Many large earthquakes of $M \geq 7.0$ are not preceded by foreshocks, even if the seismograph network is capable of detecting shocks of $M < 3.0$. Therefore the magnitude difference between the mainshock and the largest foreshock must be larger than 4 in these cases.

Temporal distributions of foreshocks are also quite variable. Foreshock sequences may show any pattern shown in Figure 1. Mogi (1985) classified the foreshock sequences into two types, C and D. In type C sequences, the activity increases gradually toward the mainshock. In type D sequences, the mainshock occurs after the foreshock activity dies down. Although no detailed statistics are available, type D seems to form a majority of foreshock sequences.

It is striking that, if we superpose the data of foreshock–mainshock time separations from many foreshock sequences, we obtain the power-law type distribution t^{-p} similar to the aftershock temporal pattern with the time direction reversed (Papazachos, 1974; Jones and Molnar, 1976, 1979; Davis and Frohlich, 1991b; Utsu, 1992; Ogata *et al.*, 1995; Maeda, 1999). Nevertheless, the great majority of individual foreshock sequences do not fit the power-law distribution. Only a limited number of foreshock sequences or precursory seismic activities show a regular increase of activity (power-law or exponential growth) toward the mainshock (e.g., Varnes, 1989; Jaumé and Sykes, 1999; Yamaoka *et al.*, 1999).

The discrimination of foreshock sequences from earthquake swarms is a difficult problem, because no easily recognizable differences in statistical or physical properties are found between them. For further discussion on this issue and other characteristics of foreshocks, including the relation to tectonics and fault types, see Mogi (1963), Jones and Molnar (1979), von Seggern *et al.* (1981), Jones (1984), Ogata *et al.* (1995, 1996), Abercrombie and Mori (1996), and Reasenber (1999).

2.4 Earthquake Swarms

An earthquake swarm is a cluster of earthquakes in which there is no predominantly large single earthquake. Swarms are roughly divided into two types. The first type is the ordinary swarm in which the activity changes more or less irregularly (Fig. 1c) lasting a few hours to more than one year. Most swarms occurring in volcanic areas show this pattern, reflecting

the magmatic activity at depths. The second type is the successive occurrence of mainshock–aftershock sequences of similar size (Fig. 1d), which lasts several days to months.

3. Size Distribution of Earthquakes

3.1 Gutenberg–Richter Relation and its Equivalents

3.1.1 Power-Law Distribution

In general, smaller earthquakes are much more frequent than larger ones. Statistical studies of this property in late 19th century were not so successful because of the lack of adequate scale to measure the earthquake size. For historical review, see Utsu (1999), where the pioneering work of Wadati (1932) has been introduced. He adopted a power-law distribution for earthquake energy E

$$n(E) \propto E^{-w} \quad (11)$$

and estimated the value for exponent w as 1.7–2.1 or smaller by an indirect method. If the magnitude M is related to energy E (erg) by the equation of Gutenberg and Richter (1956)

$$\log E = 1.5M + 11.8 \quad (12)$$

Equation (11) is equivalent to the famous equation by Gutenberg and Richter (1944, 1949)

$$\log n(M) = a - bM \quad (13)$$

or

$$\log N(M) = A - bM, \quad N(M) = \int_M^{\infty} n(M) dM \quad (14)$$

and $w = 1 + 2b/3$. Numerous studies indicated that Gutenberg and Richter's relation (hereafter called the G-R relation) is approximately valid in most cases and the value of b falls in the range 0.6–1.1. This corresponds to a w value of 1.40–1.73.

Ishimoto and Iida (1939) showed that the maximum amplitude A recorded at a seismograph station has a power-law distribution with exponent $m = 1.74$,

$$n(A) \propto A^{-m} \quad (15)$$

This is equivalent to the G-R relation with $b = m - 1$ (Asada *et al.*, 1951), if magnitude is defined by $M = \log A + f(\Delta)$, where $f(\Delta)$ is the calibrating function for epicentral distance Δ and the b value does not vary regionally. Most m values reported hitherto fall between 1.6 and 2.1.

Since the development of the concept of fractals, many phenomena exhibiting a power-law distribution have been treated as fractals. The G-R relation has often been interpreted in terms of the power-law (fractal) statistics of faults, cracks, and fragments (e.g., Takeuchi and Mizutani, 1968). Aki (1981) related the b value and the fractal dimension D as $D = 2b$.

In these interpretations, it is implicitly assumed that each fault (or crack, or fragment) corresponds to one earthquake, i.e., the probability of earthquake occurrence is independent of the fault size. This assumption does not seem so natural.

3.1.2 Estimation of b Value

Under the assumption that the magnitude data are random samples from a population obeying the G-R relation, the method of moments (Utsu, 1965) and the method of maximum likelihood (Aki, 1965) both yield the solution

$$b = \log e / (\bar{M} - M_z) \quad (16)$$

where $\bar{M}$ is the mean magnitude of earthquakes of $M \geq M_z$ and $\log e = 0.434294$. M_z is the threshold magnitude above which the data should be complete. The standard error of the maximum likelihood estimate of b is approximately $b/\sqrt{N}$ for large N (the number of earthquakes of $M \geq M_z$). The smallness of error does not necessarily indicate the goodness of fit of the G-R relation to the data.

Since Eq. (16) is obtained for continuous exponential distribution, care must be taken when we use discrete (rounded) magnitude values. If the magnitudes are given at intervals of 0.1 as in most catalogs, and if we use the data with $M \geq 4.0$ for example, we must put $M_z = 3.95$ in Eq. (16), because $M = 4.0$ means $4.05 > M \geq 3.95$. If we use $M_z = 4.0$ in this case, the error in b value may easily reach several percent. There is another kind of error due to rounding (e.g., Tinti and Mulargia, 1987; Vere-Jones, 1989). This error is not large (usually less than 1%) if the magnitudes are given to the nearest 0.1 magnitude unit or less.

3.1.3 Temporal and Spatial Variation of b Value

Numerous papers have been published dealing with the spatial and temporal variation (or stability) of b value (e.g., Utsu, 1971; Li *et al.*, 1983; Imoto, 1987; Jin and Aki, 1989; Ogata and Katsura, 1993). For example, temporal changes in b value for background seismicity prior to large earthquakes have occasionally been reported (e.g., Smith, 1986, 1998; Trifu and Radulian, 1991; Imoto, 1991). Smaller b values for foreshocks than those for aftershocks and background seismicity have also been reported (e.g., Suyehiro *et al.*, 1964; Berg, 1968; Wu *et al.*, 1976; Molchan and Dimitrieva, 1990; Molchan *et al.*, 1999). However, we notice that many foreshock sequences have normal b values, and some earthquake swarms with small b values are not followed by future large earthquakes.

Spatial variations of b value have been studied for various regions of the world and for various focal depth ranges (Ogata *et al.*, 1991; Frohlich and Davis, 1993; Okal and Kirby, 1995; Wiemer and Wyss, 1997; Molchan *et al.*, 1997; Wiemer *et al.*, 1998, and many others). However, universally recognizable

regularities are relatively few. Some authors have argued against the regional variation of size distribution (e.g., Kagan, 1997, 1999).

To test the significance of the difference in b values between two earthquake groups, a method based on the F -distribution has been used (Utsu, 1966). A method using Akaike Information Criterion (AIC) (see Chapter 82 by Vere-Jones and Ogata) is simpler (Utsu, 1992, 1999). Of course these tests assume the G-R relation. If this assumption is not valid, it is possible that the two groups have nearly equal b values calculated from Eq. (16) but the size distributions are quite different.

3.2 Modified Equations

Although the G-R relation fits the data fairly well in many cases, significant deviation from it has often reported. The $\log n(M)$ (or $\log N(M)$) versus M plots for some data sets show considerable curvature, though the G-R relation predicts a straight line with slope of $-b$.

Various modifications of the G-R relation have been proposed to represent such curved distributions (see a review by Utsu, 1999). The simplest one is the truncated G-R relation, i.e., $\log n(M) = a - bM$ for $M \leq M_{\max}$ and $n(M) = 0$ for $M > M_{\max}$. The maximum likelihood estimate of b in this case is somewhat different from that calculated from Eq. (16) (e.g., Page, 1968). If the truncated G-R relation is valid, the regional variation in b value calculated from Eq. (16) may be caused by the regional difference in $M_{\max}$ rather than the b slope in the range below $M_{\max}$.

The power-law distribution of energy or moment tapered by an exponential function used by Kagan (1991a, 1993, 1997) has the form (Gamma distribution)

$$n(E) = CE^{-w} \exp(-E/E_{\max}) \quad (17)$$

This is equivalent to

$$\log n(M) = a - bM - k10^{1.5M} \quad (18)$$

where $b = 1.5(w - 1)$ and $k = 10^{-1.5M_{\max}} \log e$ ($M_{\max}$ is the magnitude corresponding to $E_{\max}$). This is a generalized form of an equation for a branching model (Otsuka, 1972) derived by Saito *et al.* (1973), Vere-Jones (1976), and Maruyama (1978), in which b takes a value of 0.75.

Another modification is the power-law distribution tapered by a logarithmic function

$$n(E) = CE^{-w} \ln(E_{\max}/E), \quad (n(E) = 0 \text{ for } E \geq E_{\max}) \quad (19)$$

which is equivalent to the equation proposed by Utsu (1971)

$$\log n(M) = a - bM + \log(M_{\max} - M) \quad (20)$$

It is possible to obtain the maximum likelihood estimates of the parameters of Eqs. (17)–(20) and some other equations including those proposed by Lomnitz-Adler and Lomnitz

FIGURE 3 Frequency-magnitude distribution for earthquakes in the world for the years 1977–1997. The magnitude used is the moment magnitude (M_w) converted from seismic moments given in the Harvard University CMT catalog. Open and solid circles denote the frequency per 0.1 magnitude unit and cumulative frequency, respectively. Curves for Eqs. (18) and (20) fitted to the data are shown.

(1979), Makjanić (1980), Anderson and Luco (1983), and Seino *et al.* (1989) together with the AIC values for a given set of magnitude data. Computer programs are available in *IASPEI Software Library* Vol. 6 (Utsu and Ogata, 1997). We can compare AIC values for different equations and find the best fitting equation. For model selection criteria using AIC, see Chapter 82 by Vere-Jones and Ogata. Utsu (1999) provides actual examples.

Figure 3 shows the distribution of M_w for recent earthquakes in the world. The curves represent Eqs. (18) and (20) fitted to the data. If the complete data in the 1950s and 1960s were available, the distribution would be closer to the G-R relation (straight line), since several great earthquakes of $M_w = 8.7$ – 9.5 occurred during 1952–1965 (Kanamori, 1977).

4. Temporal Distribution of Earthquakes

4.1 Stationary Poisson Process

The simplest reference model for the distribution of earthquakes in time is the stationary Poisson process, in which all events occur independently and uniformly in time. This process

is characterized by only one parameter, the rate of occurrence ν . If N events occur during a sufficiently long time interval T , the rate ν is given by $\nu = N/T$. For the stationary Poisson process, the frequency of events n in an interval of length Δt has a Poisson distribution

$$f(n) = (\nu \Delta t)^n \exp(-\nu \Delta t) / n! \quad (21)$$

The time interval τ between successive events (interevent time) has an exponential distribution

$$w(\tau) = \nu \exp(-\nu \tau) \quad (22)$$

The power spectrum of a point process t_k (occurrence time of the k th event; $k = 1, 2, \dots, N$) is given by

$$S(\omega) = \left| \sum_{k=1}^N \exp(-i\omega t_k) \right|^2 / N \\ = \left\{ \left(\sum_{k=1}^N \cos \omega t_k \right)^2 + \left(\sum_{k=1}^N \sin \omega t_k \right)^2 \right\} / N \quad (23)$$

where ω denotes the angular frequency. For a Poisson process, $S(\omega)$ is independent of ω and has an exponential distribution of parameter 1. Therefore the probability that $S(\omega)$ for a randomly chosen ω exceeds a certain value α is $e^{-\alpha}$ (Schuster, 1897).

4.2 Time-dependent Poisson Process

If the rate of occurrence changes gradually with time as expressed by $n(t)$, but can be regarded as a stationary Poisson process for a sufficiently short time span, the process is called a time-dependent Poisson process. For this process, distribution of number of events in a time interval from t_1 to t_2 ($\Delta t = t_2 - t_1$) is given by

$$f(n) = \int_{t_1}^{t_2} \{n(t)\Delta t\}^n \exp\{-n(t)\Delta t\} dt / (n!\Delta t) \quad (24)$$

The distribution of interevent times in a time interval from t_1 to t_2 is given by

$$w(\tau) = \int_{t_1}^{t_2} n(t)^2 \exp\{-n(t)\tau\} dt / \int_{t_1}^{t_2} n(t) dt \quad (25)$$

The modified Omori relation [Eq. (1)] is an example of the time-dependent Poisson process. Ouchi (1982) discussed the function

$$n(t) = n_0 / [1 - (n_0/k)^\alpha] \exp(-rt) + (n_0/k)^\alpha]^{-\alpha} \quad (26)$$

which is the solution of a logistic equation (Goel *et al.*, 1971)

$$dn(t)/dt = r[1 - \{n(t)/k\}^\alpha] / \alpha \quad (27)$$

Equation (26) can represent various temporal patterns of seismic activity by using different ranges of k , α , r and n_0 [the initial

value of $n(t)$]. For $n(t) \gg k$, it is approximately the same as the modified Omori relation with $p = \alpha^{-1}$. For $n(t) \ll k$, $n(t) \propto \exp(rt/\alpha)$ which represents some foreshock activities. For further development along this line, see Ouchi (1993).

Tomoda (1954) reported a power-law distribution of interevent times, $w(\tau) \propto \tau^{-q}$ ($q = 1 \sim 2$), for some volcanic swarms and aftershock sequences. Senshu (1959) interpreted Tomoda's result using Eq. (25) with $n(t)$ of the modified Omori relation. Utsu (1970) showed that Eqs. (24) and (25) with $n(t) = Kt^{-p}$ ($t_1 \rightarrow 0$, $t_2 \rightarrow \infty$) yield power-law distributions $f(n) \propto K'n^{-r}$ (for $n \geq$ about 4) and $w(\tau) \propto K''\tau^{-q}$, where $r = 1 + p^{-1}$ and $q = 2 - p^{-1}$ ($q + r = 3$).

4.3 Fractal Analyses in Time

Self-similarity or fractal structure in temporal distribution of earthquakes has sometimes been recognized. Various methods have been used for estimating the fractal dimension in time. These include the use of autocovariance function and variance-time curve for time intervals, box counting, periodogram (spectral curve), etc. Relevant papers are Smally *et al.* (1987), Kagan and Knopoff (1987), Ogata and Abe (1991), Kagan and Jackson (1991), Papadopoulos and Dedousis (1992), Godano and Caruso (1995), Lee and Schvarcz (1995), Luongo and Mazzarella (1997), and Wang and Lee (1997), among others.

The fractal dimensions obtained for various catalogs lie mostly between 0.1 and 0.5. Kagan and Jackson (1991) showed long-term clustering (hundreds days or more) with fractal dimension of 0.8–0.9. Ogata and Abe (1991) have also shown long-term dependence.

4.4 Recurrence Models

4.4.1 Renewal Process

Temporal distribution of earthquakes, especially so-called characteristic earthquakes recurring on a specific fault or fault segment, often represented by a renewal process. It is defined as a series of events in which interevent times are independently and identically distributed. In general, the relations between density function of the distribution $w(t)$, hazard rate $\mu(t)$, and survivor function (reliability function) $\phi(t)$ are as follows.

$$w(t) = \mu(t)\phi(t) = -d\phi(t)/dt \quad (28)$$

$$\mu(t) = d \ln \phi(t) / dt = w(t) / \int_t^\infty w(t) dt \quad (29)$$

$$\phi(t) = \exp\left\{-\int_t^\infty \mu(t) dt\right\} = \int_t^\infty w(t) dt \quad (30)$$

The probability that the next earthquake occurs in an interval from t to $t+u$ is given by

$$p(u|t) = 1 - \exp\left\{-\int_t^{t+u} \mu(t) dt\right\} = 1 - \frac{\phi(t+u)}{\phi(t)} \quad (31)$$

TABLE 1 Some interevent distributions for renewal models^a

Name	Density of time interval $w(t)$	Survivor function $\phi(t)$	Hazard rate $\mu(t)$	Expectancy of time interval $E[t]$
Poisson	$\alpha \exp(-\alpha t)$	$\exp(-\alpha t)$	α	$1/\alpha$
Weibull	$\alpha \beta t^{\beta-1} \exp(-\alpha t^\beta)$	$\exp(-\alpha t^\beta)$	$\alpha \beta t^{\beta-1}$	$\alpha^{-1/\beta} \Gamma(1/\beta + 1)$
Lognormal	$1/(\sqrt{2\pi}\sigma t) \exp\{-(\ln t - m)^2/(2\sigma^2)\}$	$1 - \Phi\{(\ln t - m)/\sigma\}$	$w(t)/\phi(t)$	$\exp(m + \sigma^2/2)$
Gamma	$c(ct)^{r-1} \exp(-ct)/\Gamma(r)$	$\Gamma(r, ct)/\Gamma(r)$	$c(ct)^{r-1} \exp(-ct)/\Gamma(r, ct)$	r/c
EP (Doubly exponential)	$\exp[(A/b)\{1 - \exp(bt)\} + bt]$	$\exp[(A/b)\{1 - \exp(bt)\}]$	$A \exp(bt)$	$(1/b) \exp(A/b) \text{Ei}(-A/b)$

^a $\Phi(\cdot)$, $\Gamma(\cdot)$, $\Gamma(\cdot, \cdot)$, and $\text{Ei}(\cdot)$ denote the error integral, the gamma function, the incomplete gamma function, and the exponential integral, respectively.

The mean time interval is given by

$$E[t] = \int_0^\infty \phi(t) dt \quad (32)$$

The functional forms for five distributions are given in Table 1. The Weibull distribution has been used by Rikitake (1974), Sykes and Nishenko (1984), Utsu (1984), Parvez and Ram (1997), and others. The lognormal distribution has been used by Terada (1918), Nishenko and Bulland (1987), Goes (1996), and others. The Gamma distribution has been used by Udías and Rice (1975), Utsu (1984), Parvez and Ram (1997), and others. In the EP model (Utsu, 1972a,b, 1984), the hazard rate increases exponentially with time as $\mu(t) = A \exp(bt)$. If the stress increases proportionally to time, and the probability of rupture is an exponential function of the stress, this model must be appropriate.

The exponential distribution (Poisson process) is a special case of Weibull distribution ($\beta=1$), or Gamma distribution ($r=1$), or the EP model ($b=0$). The ratio of the standard deviation of τ to its expectancy is given by $I=1$, $I = [\Gamma(2\beta^{-1}+1)/\Gamma^2(\beta^{-1}+1) - 1]^{1/2}$, $I = [\exp(\sigma^2 - 1)]^{1/2}$, and $I = 1/\sqrt{r}$ for exponential, Weibull, lognormal, and Gamma distributions, respectively. $I \leq 0.3$ corresponds to $\beta \geq 3.7$, $\sigma \leq 0.3$, and $r \geq 11$. Roughly speaking, events occur fairly regularly (quasi-periodically) if the parameters β , σ , and r take a value in these ranges. Great historical earthquakes of Nankai region, southwest Japan, provide a good example ($\beta=6$, $\sigma=0.18$, $r=30$, Utsu, 1984). Ogata (1999a) discussed the case in which the occurrence times of past events are uncertain, as in the case of paleoearthquakes.

Other distributions found in the seismological literature include normal distribution (must be truncated at $t=0$) and inverse Gaussian distribution (Kagan and Knopoff, 1987).

4.4.2 Other Recurrence Models

Time-predictable and slip-predictable models (Shimazaki and Nakata, 1980) for large earthquakes are recurrence models involving the earthquake size. The time-predictable model (the time interval between two large earthquakes A and B is proportional to the amount of fault slip in A) seems to provide a better fit in many cases.

Following a paper by Papazachos (1989), his group published many papers providing the empirical equations for the time interval τ to the next earthquake and the expected magnitude M_f of the next earthquake for various regions of the world. These equations express $\log \tau$ and M_f as linear functions of M_z (threshold magnitude adopted), M_p (magnitude of the last earthquake), and $\log \dot{M}_0$ (moment release rate for the region concerned). In early papers, a simple equation in the form of $\log \tau = cM_p + c_0$ was used [see the latest evaluation paper by Papazachos and Papadimitriou (1997) and references listed there].

For the slip-predictable model, see, for example, Kiremidjian and Anagnos (1984).

The stress release model (Vere-Jones and Deng, 1988; Zheng and Vere-Jones, 1991, 1994) is not a recurrence model, but it has some similarity to the above models. It is a point process model with an intensity function expressed as

$$n(t) = A \exp[\beta\{\lambda t - \sigma(t)\}] \quad (33)$$

where $\sigma(t)$ is the stress released by the earthquakes which occurred until time t , and A , β , and λ are model parameters that can be determined by the maximum likelihood method. See also Vere-Jones (1994) for an explanation of this model and more general discussion on statistical models of earthquake occurrence.

4.5 Point Process Models Incorporating the Clustering of Earthquakes

Several point process models in which the clustering of events is taken into account have been used in seismicity studies. These include the trigger model (Vere-Jones and Davies, 1966; Vere-Jones, 1970; Utsu, 1972a,b; Hawkes and Adamopoulos, 1973), a generalized Poisson process (Shlien and Toksöz, 1970; Bottari and Neri, 1983; De Natale and Zoro, 1986) which can be regarded as a simplified version of the trigger model, a kind of branching process (Kagan and Knopoff, 1981), and the ETAS model (Ogata, 1988, 1992, 1999b).

The trigger model successfully represents some non-Poissonian behavior seen in many actual seismicity data (sharp increase of the frequency of short interevent times, increase of the power spectrum toward the zero frequency, etc.) without

labeling each event as mainshock, aftershock, or isolated event.

In a self-exciting model used by Hawkes and Adamopoulos (1973), every event produces its offspring events. The occurrence rate (intensity) at time t is expressed by

$$n(t) = \mu + \sum_{t_i < t} g(t - t_i) \quad (34)$$

where μ and $g(t - t_i)$ represent the constant background activity and the activity triggered by an event at time t_i , respectively. They adopted the sum of two exponential functions for $g(t)$.

The ETAS model (epidemic type aftershock sequence model) is a self-exciting model in which the modified Omori relation combined with the G-R relation is used for $g(t)$.

$$g(t - t_i) = K \exp\{\alpha(M_i - M_z)\}(t - t_i + c)^{-p} \quad (35)$$

where M_i and t_i is the magnitude and time of the i th earthquake ($t_1 < t_2 < \dots < t_N$). N is the number of earthquakes of magnitude M_z and larger. The values of five parameters μ , K , α , p , and c , can be estimated by the maximum likelihood method. Computer programs are included in Utsu and Ogata (1997). The standard errors in the estimated values can be computed using the Hessian matrix (see Chapter 82 by Vere-Jones and Ogata). However, this software does not include the program for the computation of errors because of the limited power of the personal computers in 1993 when this software was prepared.

The ETAS model is useful in objective detection of a period of anomalously increased or decreased activity by comparing the observed rate with the rate computed from the ETAS model fitted to the observed data.

4.6 Periodicity

4.6.1 Power Spectrum for a Point Process

The periodicity of earthquake occurrences has been searched over a century, but only weak periodicity has been found in limited cases. If seismicity has a periodicity of period T_p , the power spectrum calculated from Eq. (23) has a peak at the angular frequency $\omega_p (= 2\pi/T_p)$. It is not easy to say what level of the spectral value should be used to establish the existence of periodicity. The Schuster's criterion (Section 4.1) is inadequate when the events show temporal clustering (e.g., Jeffreys, 1938; Vere-Jones and Ozaki, 1982).

Consider the case in which we analyze the events in the time span of length L and compute the power spectrum for m angular frequencies $\omega_k (= 2\pi k/L, k = 1, 2, \dots, m)$. The obtained spectral values are designated by $S_1, S_2, \dots, S_m$ in order of their strength. Schuster's criterion cannot be applied to S_1 (the highest peak), even if there is no clustering in seismicity. Instead, Fisher's criterion (1929) must be used, which gives the probability $P(g, m)$ that $S_i / \sum_{k=1}^m S_k$ exceeds a value g . See

Nowroozi (1967) and Shimshoni (1971) for the expression and numerical tables of $P(g, m)$.

4.6.2 Searching Periodicity in Time-varying and Clustered Seismicity

If the earthquakes have a tendency of clustering or the occurrence rate changes with time, the spectral level usually increases beyond the expected level for the Poisson process. For example, the theoretical spectral value for the trigger model increases with decreasing frequency from 1 at very high frequencies to $1 + A + V/(1 + A)$ at zero frequency, where A and V denote the mean and variance of the number of aftershocks following a triggering event (Vere-Jones and Davies, 1966).

Ogata (1983b) examined the periodicity hidden in time-varying seismicity with strong clustering by using a self-exciting model with intensity

$$n(t) = \mu + P_J(t) + C_K(t) + \sum_{t_i < t} g(t - t_i) \quad (36)$$

where $P_J(t)$ is a polynomial of the order J for representing the long-term trend and $C_K(t)$ is a Fourier series of the order K for representing the periodic component of suspected period T_0 . For $g(t - t_i)$ the Laguerre polynomial of order L is used.

$$g(t) = \sum_{l=1}^L a_l t^{l-1} \exp(-Ct) \quad (37)$$

By using this model, the periodic component can be separated from the trend and cluster components. Maximum likelihood estimates of $J + 2K + L + 2$ parameters and AIC are obtained for various combinations of J , K , and L , then the best combination that gives the smallest AIC can be found. If $J = 0$ in the best combination, there is no trend. If $K = 0$, the periodicity of period T_0 is rejected. Ogata (1983b) confirmed annual periodicity in shallow seismicity in western Japan. Similar studies were made by Matsumura (1986) and Ogata and Katsura (1986) for other regions (see Ogata, 1999b).

4.6.3 Reported Periodicities

Many papers have been published reporting the existence of periodicity in earthquakes of various regions and magnitude ranges. The periods reported are one year, one day, synodic month (29.530589 days), sidereal month (27.32166 days), 11 y (sunspot cycle), and others. A period around 42 min reported by Davison (1938) and later workers may correspond to a normal mode of Earth's free oscillation, but most of the periods reported by him using Schuster's criterion may be attributed to the effect of clusters in the data (see, Jeffreys, 1938).

The annual periodicity is often connected with the seasonal variation of rainfall, snow melting, and subsequent change in groundwater, because the periodicity is recognized

predominantly for inland shallow earthquakes (e.g., Oike, 1978; Ogata, 1983b; Costain and Bollinger, 1996). Seasonal variation in amplitudes of microseisms may cause the variation of the number of small earthquakes in certain catalogs. The diurnal periodicity (increased activity in nighttime) reported since old times may be attributed to human activity rather than natural reasons.

Although the periodicity in earthquake occurrences, if it exists, is usually not so strong as to affect earthquake hazard problems, it is interesting to explore the triggering mechanism and some unknown periodic phenomena occurring in the Earth's system. However, since the problem is fairly critical, careful selection and analysis of data are required to draw meaningful conclusions.

5. Spatial Distribution of Earthquakes

5.1 Spatial Patterns of Seismicity

5.1.1 Poisson Process in Space

For independently and uniformly distributed hypocenters in N -dimensional space, the N th power of the distance r from a hypocenter (or an arbitrarily chosen point) to the nearest neighbor, $s(=r^N)$, has an exponential distribution $f(s) = \lambda \exp(-\lambda s)$, where λ is the mean number of hypocenters falling in an N -dimensional sphere of unit radius. The number n of hypocenters falling in an N -dimensional volume of a fixed size has a Poisson distribution.

The actual hypocenters (or epicenters) are not distributed randomly. Earthquakes are associated with tectonic structures of various scales from long plate boundaries to small local fracture systems. The stationary Poisson process in space seems to be a less plausible model than the stationary Poisson model in time. The nonhomogeneous Poisson process may be a simplest practical model in space.

5.1.2 Representation Using Contour Lines

Spatial variation of the density of hypocenters can be represented by smoothed contour lines. See Ogata and Katsura (1988) for a technique using a Bayesian procedure and B-spline functions. The smoothed spatial distribution of a seismicity parameter can be obtained in a similar way. Spatial variation of b value studied by Ogata *et al.* (1991) is an example. See Vere-Jones (1992) for reviews of these and relevant methods.

5.2 Fractal and Nonfractal Distributions in Space

Tomoda (1952) divided a seismic area of Kanto, Japan, into many narrow zones of equal widths by parallel lines and measured the distance s between the neighboring epicenters

in each stripe. The frequency of s has a power-law dependence on s

$$f(s) \propto s^{-q} \quad (q \cong 1.6) \quad (38)$$

Another power-law distribution was found by Suzuki and Suzuki (1965) for the number n of epicenters of shallow earthquakes in the world and in Japan falling in areas of a fixed size,

$$f(n) \propto n^{-r} \quad (r \cong 1.4) \quad (39)$$

Equations (38) and (39) suggest a fractal distribution of epicenters. Fractal analyses of spatial distribution pattern of earthquakes are usually made by using either the box counting method (e.g., Sadovalskiy *et al.*, 1984; Hirata, 1989; Robertson *et al.*, 1995) or the spatial correlation function (e.g., Kagan and Knopoff, 1980; Henderson *et al.*, 1994; Volant and Grasso, 1994). The slope of spectral curves has also been used (Ogata and Katsura, 1991). The estimates of fractal dimension range from 1.0 to 2.0 for epicenter distribution (2D). Those for hypocenter distribution (3D) scatter widely from 1.0 to nearly 3.0, probably because the vertical distribution of hypocenters is highly variable from region to region.

The spatial correlation function $n(r)$ is the number of hypocenters in unit volume at distance r from a hypocenter. For a stationary Poisson process, $n(r) = \rho$ (constant). For a fractal distribution in N -dimensional space, $n(r) \propto r^{D-N}$, where D is the fractal dimension. The total number of hypocenters within the distance of r from a hypocenter is proportional to r^D .

Some papers discuss the relation between fractal dimension D of hypocenter distribution and the b value of magnitude-frequency distribution for general seismic activity, aftershock sequences, and acoustic emission (AE) events observed in rock fracture experiments [see Hirata (1989), Ogata and Katsura (1991), Henderson *et al.* (1992, 1994), De Rubeis *et al.* (1993), Volant and Grasso (1994), Öncel *et al.* (1996), Guo and Ogata (1997), and Ponomarev *et al.* (1997)].

Other studies of fractal or nonfractal distribution of hypocenters include Tamaki (1961), Francis and Porter (1971), Kagan (1981a,b), Ouchi and Uekawa (1986), Eneva and Pavlis (1988), Frohlich and Davis (1990), Ogata and Abe (1991), Hirata and Imoto (1991), Eneva *et al.* (1992), Hirabayashi *et al.* (1992), and Eneva (1996).

6. Spatiotemporal Seismicity Patterns

6.1 Correlation and Migration of Seismicity

Synchronous or alternate occurrences of large earthquakes or increased seismicity between two adjacent or separate regions have sometimes been reported (e.g., Mogi, 1973; Mantovani

and Albarello, 1997). Migration of seismicity is another noticeable phenomenon (e.g., Mogi, 1968b; King and Ma, 1988). However, many of these patterns do not persist permanently and successful predictions based on these patterns are rather rare.

Relatively clear correlation is seen in subduction zones. Tens of papers have been published reporting the correlation between interplate earthquakes and intraplate earthquakes in the overriding plate and between shallow interplate or intraplate earthquakes on the trench side and intermediate or deep earthquakes in the subducting plate (Mogi, 1973; Utsu, 1975; Seno, 1979; Ogata *et al.*, 1982; Mizoue *et al.*, 1983; Ohtake, 1986; Hori and Oike, 1996). Mostly negative results have been reported for correlation between large shallow and intermediate-depth earthquakes in a global survey by Astiz *et al.* (1988).

Since the earthquakes have a tendency to clustering, the correlation coefficient between two regions easily exceeds the level expected for the Poissonian occurrence, even if there is no correlation between the two. To analyze the interaction between earthquakes in two regions, Ogata *et al.* (1982) expressed the seismicity rate of the first region by Eq. (36) with an additional term $\sum_{t_j < t} h(t - t_j)$ for the seismicity excited by earthquakes in the second region. Using a Laguerre polynomial of order M for $h(t)$, they obtained the maximum likelihood estimates of the coefficients of each term for various combinations of J , K , L , and M for a given set of data. If the smallest AIC is attained for a combination in which $M \geq 1$, we can conclude that the seismicity in the first region is affected by the seismicity in the second region. Similar studies were made by De Natale *et al.* (1988) and Mucciarelli *et al.* (1988) (also see Ogata, 1999b).

There are also tens of papers dealing with migration of seismic activity. However, the reported velocities differ very widely from 1 to $5 \times 10^4 \text{ km y}^{-1}$. This scatter is unbelievably large for phenomena caused by a single physical mechanism, though velocities between 2 and 200 km y^{-1} are relatively frequent.

6.2 Regional Seismicity Patterns Preceding Large Earthquakes

Since seismicity varies temporally and spatially in a complex manner, unusual patterns before many large earthquakes can be found rather easily. These patterns include quiescence and activation of various spatial and time scales and more complicated patterns such as doughnuts, migration toward the mainshock hypocenter, increase in clustering, etc. However, the relation between these patterns and the occurrence of large earthquakes is not so definite.

More than 200 papers had been published by the end of 1999, reporting the seismic quiescence preceding some large earthquakes in many parts of the world (e.g., Wyss and Martirosyan, 1998), since Inouye (1965) reported quiescence

before three $M=7-8$ earthquakes in Japan. Only a few cases are known where the quiescence was recognized in advance of the mainshock (e.g., Utsu, 1972b; Ohtake *et al.*, 1977; Wyss and Burford, 1987; Kisslinger, 1988; Matsu'ura *et al.*, 1995).

Due to the existence of remarkable clustering of earthquakes, fluctuation of activity beyond the level expected from the stationary Poisson process easily occurs. To find a period or region of significantly increased or decreased seismicity, we must use a declustered catalog or a model that incorporates the effect of clustering, such as the ETAS model (Ogata, 1992, 1999b).

Precursory activation of seismicity other than the immediate foreshocks has also been studied by many investigators. The precursory seismicity pattern reported by Keilis-Borok and coworkers (e.g., Keilis-Borok and Malinovskaya, 1964; Keilis-Borok and Kossobokov, 1990; Kossobokov *et al.*, 1990; Keilis-Borok, 1996) can be regarded as a kind of activation, though the pattern is complicated to explain in short. Nearly one hundred papers describing the methods for detecting the pattern, case studies in various region of the world, and evaluations of the results have been published. One of the standard algorithms for this approach called M8 which aims the long-term prediction of large earthquakes is included in Kossobokov (1997).

A kind of precursory activation of seismicity near the mainshock epicenter has been observed in Japan (Sekiya, 1976) and New Zealand (Evison, 1977). Evison called this "precursory swarm." See Evison and Rhoades (1997) for a recent re-evaluation of this pattern in New Zealand. Similar patterns have been reported from Central Asia (e.g., Kristy and Simpson, 1980), China (e.g., Zhou *et al.*, 1995), India (e.g., Gupta and Singh, 1989), and some other regions.

6.3 Space-time Point-process Models

There are some point-process models for seismicity involving both space and time. They are inevitably more complicated than the models in time or space domain alone. See the following references for further details: space-time correlation functions by Kagan and Knopoff (1976), Vere-Jones (1978), Chong (1983), and Reasenber (1985); the branching models by Kagan and Knopoff (1976, 1977, 1978, 1980, 1981) and their extension by Kagan (1991b); the space-time version of a self-exciting model by Musmeci and Vere-Jones (1992) and that of the ETAS model by Rathbun (1993) and Ogata (1998).

7. Concluding Remarks

Most studies of seismicity are more or less statistical, because they deal with earthquake generation in groups. Thousands of papers relevant to statistical features of seismicity have been published. Only a small fraction of them are quoted in this chapter. Some review articles (e.g., Kagan, 1994; Vere-Jones,

1994; Main, 1996; Koyama, 1997; Ogata, 1999b) may supplement this chapter.

The level of seismicity and its statistical properties may be affected by environmental conditions, such as stress, temperature, pore fluid pressure, mechanical and rheological properties of rocks, etc. as well as the large-scale tectonic regimes. Numerous papers have been published discussing the relation of seismicity to these conditions and the physical mechanisms that cause the observed regularities in seismicity. For example, the questions of why the G-R relation and the modified Omori relation are universally observed from shallow earthquakes to very deep earthquakes and from AE events generated in laboratory experiments to large earthquakes, what factors control the b value and p value, etc. have been discussed using various approaches. In spite of these efforts, there remain many problems of describing and interpreting various characteristic features of seismicity.

Acknowledgments

I thank L. Knopoff and D. Vere-Jones for helpful reviews of the manuscript.

Relationships between Magnitude Scales

Tokuji Utsu

The University of Tokyo, Tokyo, Japan

1. Introduction

This chapter is a revision of the author's paper (Utsu, 1982b) having the same title. The reinvestigation using both previously used and newly added data has brought no significant change in the conclusions of the previous paper. Slightly modified curves for the relationships are presented. Since the previous paper was written in Japanese, some of the descriptions are repeated. However, materials that interest only workers of historical earthquakes in Japan are much simplified or omitted. The previous paper deals only with shallow earthquakes. Earthquakes of all depths are included in this chapter.

The magnitude scales used today stem from the one introduced by Richter (1935). This scale was designed for earthquakes in southern California recorded by the network of Wood–Anderson seismometers. This scale has been extended by later researchers in many ways to apply to the data produced in various observational environments. For example, the surface-wave magnitude and the body-wave magnitude were proposed by Gutenberg (1945a) and Gutenberg (1945b,c), respectively. These new scales were constructed, in principle, to provide the equal magnitude values to the same earthquakes or the earthquakes which radiated the equal amount of energy. However, systematic bias actually exists between the newly introduced scales and the reference magnitude scale.

The magnitude determined according to Richter's original definition is usually denoted by M_L , the magnitude calculated from the amplitudes of surface waves using the formula of Gutenberg (1945a) is denoted by M_S , and the magnitude determined from the amplitude/period ratio of P and/or S waves using the table or charts provided by Gutenberg (1945b,c; Gutenberg and Richter, 1956b) is denoted by m_B . These three magnitudes are denoted simply by M in the papers by Gutenberg (1945a,b,c), because these were considered to be equivalent. However, the subsequent studies showed that there

are systematic differences between M_L , M_S , and m_B . In a paper by Gutenberg and Richter (1956b), which first used these notations, we find the following equations.

$$m_B = 0.63 M_S + 2.5 \quad (1)$$

$$M_S = 1.27(M_L - 1) - 0.016 M_L^2 \quad (2)$$

More than 100 such equations or curves relating the different magnitudes have been published (see Figures in Section 4).

To make matters more complicated, the notations M_L and M_S are sometimes used for magnitudes other than those determined according to the original definition of Richter (1935) and Gutenberg (1945a). The original body-wave magnitude m_B is measured by using medium-period body waves, but the body-wave magnitudes m_b (or M_b) used in PDE (USGS) and ISC catalogs are measured by using the first 5 sec of short-period P waves. This yields a considerable difference between two body-wave magnitudes m_B and m_b .

The problems of relationships between various magnitude scales have been discussed in several papers, some of which contain theoretical consideration on the basis of the seismic source spectra (e.g., Aki, 1967, 1972; Kanamori and Anderson, 1975; Geller, 1976; Noguchi and Abe, 1977; Chen and Chen, 1989). These studies successfully explain some features of magnitude scales, such as the different degrees of saturation of scales for large earthquakes. Here we take only the empirical approach without making the theoretical explanation of the results.

The empirically obtained curves for the relationship between two magnitude scales represent earthquakes with average source characteristics. Significant deviation of a data point from the curve can usually be attributed to anomalous source characteristics of the event such as a nuclear explosion

or a tsunami earthquake, but no further discussion of this problem will be given here.

2. A Brief Survey of Various Magnitude Scales

2.1 Local Magnitude: M_L

This is the magnitude determined by using the equation

$$M_L = \log A + f(\Delta) \quad (3)$$

where A is the maximum trace amplitude in μm (single component) recorded by the standard W-A (Wood–Anderson) seismometer and $f(\Delta)$ is the empirically determined calibrating function of epicentral distance Δ . Richter (1935) gives a table of $f(\Delta)$ for local earthquakes in southern California ($\Delta = 30\text{--}600\text{ km}$). $f(\Delta)$ is adjusted to be 0 at $\Delta = 100\text{ km}$ according to the definition of the scale.

W-A seismometers had been operated for many years in a few regions including southern and central California and New Zealand. Magnitudes reported from these networks were regarded as genuine M_L . It is also possible to determine M_L by using simulated W-A seismograms, which are synthesized from seismograms recorded with seismographs of different response characteristics (e.g., Bakun and Lindh, 1977; Kanamori and Jennings, 1978; Jennings and Kanamori, 1979; Peppin and Bufe, 1980; Uhrhammer and Collins, 1990; Alsaker *et al.*, 1991; Shin, 1993; Savage and Anderson, 1995; Uhrhammer *et al.*, 1996; Margaris and Papazachos, 1999).

However, there are some problems in the determination of M_L . It has been suspected that the actual magnification of W-A seismometers was about 0.7 of the generally used value of 2800 (Boore, 1989; Uhrhammer and Collins, 1990). It has been pointed out that the values of M_L obtained from the data of nearby stations are somewhat smaller than those from data at distant stations. The systematic bias reaches about 0.3–0.4. This means that the attenuation of A with distance is not so strong as indicated by Richter's calibrating function. New calibrating functions have been developed for California by Bakun and Joyner (1984), Hutton and Boore (1987), and Eaton (1992). For further discussions about the calibrating function for M_L , see Haines (1981), Takeo and Abe (1981), Ebel (1982), Hadley *et al.* (1982), Luco (1982), Jennings and Kanamori (1983), Kiratzi and Papazachos (1984), Chávez and Priestley (1985), Bonamassa and Rovelli (1986), Greenhalgh and Singh (1986), Rogers *et al.* (1987), Boore (1989), Shin (1993), and Uski and Tuppurainen (1996).

In many cases (e.g., Haines, 1983; Lee *et al.*, 1990; Hatzidimitriou *et al.*, 1993; Johnston, 1996), the notation M_L is used for magnitudes determined from data of local network of short-period instruments (e.g., accelerograms) by some

practical methods without using actual or synthetic W-A seismograms.

2.2 Surface-wave Magnitude by Gutenberg (1945a): M_S

The surface-wave magnitude proposed by Gutenberg (1945a) is calculated from

$$M_S = \log A + 1.656 \log \Delta + 1.818 \quad (4)$$

where A is the amplitude in μm of surface waves of period about 20 sec (combined horizontal amplitudes) and Δ is the epicentral distance in degrees. This equation was designed mainly for the Pasadena station. It may be conceivable that somewhat different equations are more suitable to other stations. Actually, similar equations with different coefficients have been developed for other stations by several investigators.

2.3 Body-wave Magnitude by Gutenberg (1945b,c): m_B

The body-wave magnitude proposed by Gutenberg (1945b,c) is calculated from

$$m_B = \log(A/T) + q(\Delta, h) \quad (5)$$

where A and T are amplitude and period of the maximum waves of P (vertical or combined horizontal components), PP (vertical or combined horizontal components), or S (combined horizontal component), and $q(\Delta, h)$ is the calibrating function given in tables for shallow earthquakes (Gutenberg, 1945b) and by charts of complicated contours for earthquakes of all depths (Gutenberg, 1945c). These charts were revised later (Gutenberg and Richter, 1956b). The calibrating functions for body-wave magnitudes have been the subject of considerable discussion for many years. At least 30 papers have been published dealing with this problem.

2.4 Magnitude Used in Gutenberg and Richter's Book "Seismicity of the Earth" (1949, 1954): M_{GR}

In their book "Seismicity of the Earth," Gutenberg and Richter (1949, 1954) published a catalog of the World's large earthquakes. The catalog in the 1954 edition (hereafter called the G-R catalog) lists about 4000 earthquakes occurring from 1904 through 1952. M values have been assigned to most of them. Before 1917 some earthquakes of $M \geq 7.0$ are missing. Most of the earthquakes with $M \geq 6$ are listed for the period from 1932 through June 1935. Although the M values in this catalog have been used as standards for many years, no clear explanation of M is found in the book. Gutenberg and Richter (1956b) noted that "The final value given for M was a weighted mean between M_B and M_S . This may be taken as defining M without

subscript.” In this description, M_B represents the value converted from m_B by using the equation

$$M_B - m_B = (M_B - 7)/4 \quad (6)$$

Note that this equation is the same as $M_B = m_B + (m_B - 7)/3$.

However, according to Geller and Kanamori (1977) and Abe (1981a) who examined Gutenberg's worksheets, M in the G-R catalog (hereafter denoted by M_{GR}) is almost equal to M_S for shallow earthquakes ($h < 40$ km). M_{GR} is equal to m_B for earthquakes of $h = 40$ – 60 km, and M_{GR} is close to $m_B + (m_B - 7)/4$ for $h > 70$ km (Abe, 1984). Lienkaemper (1984) reported that M_{GR} is 0.16 larger than M_S on the average for surface-rupturing earthquakes.

2.5 Magnitude Used in Rothé's Book “The Seismicity of the Earth, 1953–1965” (1967): M_R

The magnitude M listed in the catalog of world's earthquakes of 1953–1965 in Rothé's book (1967) is denoted here M_R . The catalog contains about 5300 earthquakes. Almost all earthquakes of $M_R \geq 6.0$ and some smaller earthquakes are listed. It is not easy to explain briefly how M_R values have been assigned (see the description given in Rothé's book for details). For the earthquakes whose magnitude are found in the catalog of Duda (1965), the same M values have been adopted.

2.6 Surface-wave Magnitude Assigned by USGS and ISC: M_S (PDE), M_S (ISC)

Surface-wave magnitude used in PDE (USGS) and ISC catalogs are based on the formula of Vaněk *et al.* (1962).

$$M_S = \log(A/T)_m + 1.66 \log \Delta + 3.3 \quad (7)$$

where $(A/T)_m$ denotes the combined value of the maximum of amplitude/period ratios of horizontal components of the surface waves (A in μm , T in sec) and Δ is the epicentral distance in degrees. This formula, often called the Prague formula, was recommended by IASPEI at the meeting held in Zürich in 1967 and also called the IASPEI formula. In this recommendation (see e.g., Båth, 1981), the waves are restricted to Rayleigh waves of period 20 ± 3 sec and the range of Δ is limited to 20° – 160° , whereas no such restrictions are imposed on the original Prague formula. USGS and ISC have assigned the surface-wave magnitudes of relatively large earthquakes since 1968 and 1978, respectively. They are denoted here M_S (PDE) and M_S (ISC). Until the middle of 1975, the combined horizontal amplitude/period ratios of surface waves (not restricted to Rayleigh waves) of $T = 20 \pm 2$ sec were used in M_S (PDE). Later the vertical component data have been used. In determining M_S (ISC), both horizontal and vertical data in the period range from 10 to 60 sec and the distance range from 5° to

160° are used. Therefore, the original Vaněk *et al.* (1962) formula, the IASPEI recommendation, the conditions adopted by USGS and ISC may yield slightly different M_S values for the same earthquake.

The Vaněk *et al.* (1962) formula [Eq. (7)] is not perfectly consistent with the Gutenberg formula [Eq. (4)]. If $T = 20$ is put in Eq. (7), we obtain $M_S = \log A + 1.66 \log \Delta + 2.0$. This equation gives a larger M_S value than the M_S value calculated from Eq. (4) by about 0.19 for the same data.

More than 20 formulas of the Vaněk *et al.* type with different coefficients have been proposed for specific stations, specific regions, or the whole world.

Panza *et al.* (1989) noted that the Vaněk *et al.* formula yields larger M_S values with increasing epicentral distance. The difference of M_S determined from data at $\Delta = 30^\circ$ and $\Delta = 140^\circ$ is about 0.4. According to Herak and Herak (1993), the average difference of M_S at 20° and 160° reaches 0.5. The coefficient of $\log \Delta$ in Eq. (7), 1.66, seems too large. Herak and Herak (1993) proposed a formula $M_S = \log(A/T)_m + 1.094 \log \Delta + 4.429$ (Δ : 20° – 160°). The modified formulas proposed by Nuttli and Kim (1975), Thomas *et al.* (1978), Christoskov *et al.* (1985), and Rezapour and Pearce (1998) also have the coefficients of around 1.1.

2.7 Body-wave Magnitude Assigned by USGS and ISC: m_b (PDE) and m_b (ISC)

Body-wave magnitudes have been published in PDE since 1963 and in ISC since 1964. These are based on the method by Gutenberg (1945c) with the revised chart for $q(\Delta, h)$ of Gutenberg and Richter (1956b). The notations m_b and M_b are used in respective publications. These magnitudes are represented here by m_b (PDE) and m_b (ISC). There is very small but persistent bias between m_b (PDE) and m_b (ISC) (as shown in Section 5 of the full manuscript on the attached Handbook CD, under the directory \44Utsu3).

There are magnitude-dependent systematic differences between m_b and m_B . This is because m_b uses the amplitudes and periods measured on short-period instruments and m_B uses those measured on medium-to-long-period (or broadband) instruments. The periods of P waves used in m_b determinations are around 1 sec, whereas the periods used for m_B are several to about 10 sec. The maximum amplitude of first 5 sec of P waves is used in measuring m_b . In many large earthquakes, the maximum amplitude appears later than 5 sec after the initial arrival.

2.8 Moment Magnitude: M_W

To represent the size of an earthquake as a dislocation phenomenon along a fault, the seismic moment (M_0) is the most adequate measure. The level of the low-frequency end of seismic spectrum is controlled by the seismic moment.

Kanamori (1977) compared the earthquake energy-moment relation

$$E_S = (\Delta\sigma/2\mu)M_0 \quad (8)$$

where $\Delta\sigma$ is the stress drop and μ is the rigidity, with the magnitude-energy relation (Gutenberg and Richter, 1956b)

$$\log E_S = 1.5 M_S + 11.8 \quad (9)$$

When E_S and M_0 are expressed in erg and dyne cm, respectively, the average value of $\Delta\sigma/2\mu$ in Eq. (8) is approximately equal to 1.0×10^{-4} . If this value is used in Eq. (8), we obtain

$$\log M_0 = 1.5 M_S + 16.1 \quad (10)$$

It is known that M_S value saturates for great earthquakes (M_0 about 10^{29} dyne cm or more) such as the 1957 Aleutian, 1960 Chile, and 1964 Alaska earthquakes. Equations (9) and (10) do not hold for such great earthquakes. If a new magnitude scale using the notation M_W is defined by

$$\log M_0 = 1.5 M_W + 16.1 \quad (11)$$

the new magnitude M_W is equivalent to M_S within the limit of saturation and provides a reasonable figure even for great earthquakes (Kanamori, 1977).

Hanks and Kanamori (1979) defined the moment magnitude by

$$M = \frac{2}{3} \log M_0 - 10.7 \quad (12)$$

Equation (12) is the same as $\log M_0 = 1.5 M + 16.05$. Both M_W and M have been used in the name of moment magnitude in the literature, and the notation M has often been replaced by M_W . If M_W is given to the first decimal place, about 10% of earthquakes have different M_W values by 0.1 depending on whether Eq. (11) or Eq. (12) be used. Moreover, some workers use $\log M_0 = 1.5 M_W + 16.0$.

There are many empirical equations that relate various magnitudes to M_W (see Figures in Section 4). It may be possible to convert a magnitude to M_W by using these equations. Refined methods have been proposed to obtain a magnitude equivalent to M_W without measuring the seismic moment by a standard procedure (e.g., Mahdyar *et al.*, 1986). Although, it is quite reasonable to design a magnitude-scale equivalent to the moment magnitude, it may be confusing to use the term “moment magnitude” or the notation M_W for such a converted or simulated magnitude.

2.9 Tsunami Magnitude M_t

Abe (1979a, 1981b) defined the tsunami magnitude M_t for representing the magnitude of a tsunami as well as the magnitude of an earthquake which generates the tsunami. This magnitude is based on the recorded wave heights of a tsunami. The scale is so constructed that M_t agrees with the moment magnitude M_W [see also Abe (1988, 1989, 1994)].

2.10 Magnitude Assigned by the Japan Meteorological Agency M_J

The Japan Meteorological Agency (JMA) (called the Central Meteorological Observatory until 1956) keeps the nationwide seismograph network in Japan and publishes the observational data since 1885. The magnitudes assigned to earthquakes listed in the JMA catalog since 1926 are based on the formulas originally designed to provide equivalent magnitude values to M_{GR} . For details, see “Introductory Notes” of a January issue of Seismological Bulletin of JMA in recent years.

2.11 Kawasumi's Magnitude M_K

The original Kawasumi magnitude (Kawasumi, 1943) was defined as the seismic intensity in the JMA scale at the epicentral distance of 100 km, I_{100} . Kawasumi (1951) devised a formula that converts I_{100} into a value equivalent to M_{GR} . The converted value usually denoted by M_K . The conversion formula is $M_K = 0.5 I_{100} + 4.85$.

Values of M_K for significant earthquakes in historical times have been published in “Rikansenpyo (Science Chronicle)” since 1952. The M_K values of about 3900 earthquakes in Japan for the years 1885–1943 are included in a JMA catalog published in 1952. However, M_K values in this catalog are unreasonably large, especially for events before 1914. Utsu (1979, 1982b) provided a detailed explanation how and why these M_K values were so strongly biased.

2.12 Magnitude for Earthquakes in Japan in the Years 1885–1925, M_U and M_A

Until 1979 no reliable magnitudes values had been available for most of the earthquakes in Japan during 1885–1925. In the catalog of Utsu (1979, 1982a, 1988), magnitudes determined by the formula used in JMA have been given to all earthquakes of $M \geq 6.0$ and smaller ones accompanied by damage in Japan. Abe (1979b) also published a magnitude catalog of damaging earthquakes in Japan between 1901 and 1925 based on the Vaněk *et al.* (1962) formula. These two magnitudes, denoted by M_U and M_A here, agree fairly closely with almost no systematic differences (Utsu, 1982b).

3. Relationship Between Various Magnitude Scales

3.1 Data Sources

The magnitude values taken from the following sources are considered here.

M_W : The seismic moments given in the CMT catalog of Harvard University have been converted into M_W to the second decimal place by using Eq. (11) for earthquakes of 1977–1997 and $M_W \geq 5.0$. A total of 14 416 events.

For 1901–1976, Kanamori's compilation (1977) of M_W of 51 great shallow earthquakes is used.

M_{GR} : Taken from Gutenberg and Richter (1954). A total of 3513 events during 1904–1952. The data are not complete even in the range of $M_{GR} \geq 7.0$, but many events with $M_{GR} < 7.0$ are included.

M_R : Taken from Rothé (1967). A total of 5353 events during 1953–1965. Almost complete for $M_R \geq 6.0$. Many events with $M_R < 6.0$.

M_S : Taken from Abe (1981a, 1984) and Abe and Noguchi (1983a,b). A total of 1047 events during 1901–1980. Mostly $M_S \geq 7.0$.

m_B : Taken from Abe and Kanamori (1979) and Abe (1981a, 1982, 1984). A total of 1290 events during 1901–1980. Mostly $M_B \geq 7.0$.

$M_S(ISC)$, $m_b(ISC)$: Taken from ISC catalog for 1964–1995. A total of 113 349 events with $m_b(ISC) \geq 4.5$.

$M_S(PDE)$, $m_b(PDE)$: Taken from PDE (USGS) for 1964–1997. A total of 109 582 events with $m_b(PDE) \geq 4.5$.

M_J : Taken from the catalog of the Japan Meteorological Agency for earthquakes in and near Japan (1926–1997). For earthquakes in 1901–1925, Utsu's catalog (1982a, 1985, 1988) is used. A small portion of the magnitudes given in Utsu's catalog are not determined by the same method as used in JMA. These magnitudes are not used here or replaced by those determined by the JMA method (Utsu, 1982b). A total of 1710 events of $M_J \geq 6.0$ for 1901–1997. A total of 4825 events of $M_J \geq 5.0$ for 1926–1997. A total of 17 178 events of $M_J \geq 4.0$ for 1964–1997.

M_i : Taken from Abe (1979a, 1981b, 1988). A total of 141 events during 1901–1984.

For M_L , the California earthquakes included in the USGS earthquake database (data from CDMG catalog are listed)

FIGURE 1 Curves for the average magnitude differences. Variations of $M_S - M_W$, $m_B - M_W$, $m_b - M_W$, $M_L - M_W$, and $M_J - M_W$ with M_W (or $\log M_0$) are shown.

have been examined for 2396 events of M_L (PAS or BRK) ≥ 4.0 during 1932–1974, but only a small number of shocks are found whose magnitudes were also given in the G-R, or, Rothé, or Abe catalog. Some M_L values for large earthquakes may not be genuine ones determined from the W-A seismograms. For example, the catalog gives $M_L = 7.7$ for the 1952 Kern County earthquake, but this seems to be the M_{GR} value. The simulated W-A seismograms yield $M_L = 7.2$ (Kanamori and Jennings, 1978). No direct comparison between M_L and other magnitudes has been made here. The curve for M_L in Figure 1 has been tentatively drawn from published relations in various papers (see Figures in Section 4), though there are some problems in the definition and determination of M_L as described in Section 2.1.

3.2 Procedure for Constructing the Standard Curves

The main result of the previous paper (Utsu, 1982b) is a graph (called master graph) showing the relationships between M_W and $M_x - M_W$ in a range of M_W between 4 and 9, where M_x represents one of the magnitudes M_S , m_B , m_b , M_L , and M_J . The main purpose of this chapter is to present a new version of the master graph. The new graph is shown in Figure 1. The difference between the old and new curves is small, about 0.1 magnitude unit at the most.

Figures 2–16 are the scattergrams of M_x and M_y , where M_x and M_y are two magnitudes assigned to the same earthquake.

FIGURE 15 Relation between $M_S(\text{ISC})$ and M_J .

FIGURE 16 Relation between $M_S(\text{PDE})$ and M_J .

The size of a circle is so chosen that its area is proportional to the number, N , of events it represents. The dashed line represents the relation $M_x = M_y$. (Further figures are given on the attached Handbook CD.) The graphs concerning M_K or M_A (Utsu, 1982b) are omitted, because of the reason mentioned in Section 1.

A curve showing the average relation between M_x and M_y computed from the $M_x - M_W$ and $M_y - M_W$ curves in the old master graph was first drawn in the scattergram for M_x and M_y . By watching the goodness of fit of such M_x versus M_y curves, the position and shape of the $M_x - M_W$ and/or $M_y - M_W$ curves in the old master graph have been changed by trial and error to obtain a better fit in the corresponding scattergram. Such a procedure has been repeated for various combinations of magnitudes. The curves shown in Figure 1 are the final ones thus modified from the old ones.

The curves in the scattergrams (Figs. 2–16) (Figs. 2–36 on the attached Handbook CD) are not the ones fitted to individual scattergrams, but they are derived from the curves in the master graph (Fig. 1), which is the result of the adjustment considering every combination of different magnitudes. In some scattergrams, the curve shows a behavior not expected from the plotted data, but this cannot be helped for the sake of overall consistency. For example, the downward curvature in Figures 7 and 8 is not seen from the plotted data. (The main cause of this curvature is due to the data in Figure 20 on the attached Handbook CD.) The curves in Figures 7 and 8, are the same, because they are derived from the $M_S - M_W$ versus M_W curve in Figure 1.

3.3 Relationships Between Two Similar Magnitudes

3.3.1 M_{GR} for Shallow Earthquakes and M_S (1904–1952)

As shown in Figure 2, $M_{GR} = M_S$ for most earthquakes. M_{GR} values larger than M_S values are found for earthquakes occurring before 1910. These are due to overestimation of M_{GR} as remarked by Abe and Noguchi (1983b). It can be said that M_{GR} for shallow earthquakes is equivalent to M_S if these overestimated values are removed or corrected.

3.3.2 $M_S(\text{PDE})$ and $M_S(\text{ISC})$ (1976–1995)

As shown in Figure 3, there is almost no systematic difference between these two magnitudes for earthquakes of $M_S(\text{PDE})$ less than about 7.3. However, $M_S(\text{PDE})$ is larger than $M_S(\text{ISC})$ by about 0.1 on the average for $M_S(\text{PDE})$ larger than 7.4. Since these magnitudes are based on the Vaněk *et al.* (1962) formula, we use the notation $M_S(V)$ to represent both $M_S(\text{PDE})$ and

$M_S(\text{ISC})$. The standard curve labeled M_S in Figure 1 represents $M_S(\text{V})$.

3.3.3 M_S and $M_S(\text{V})$ (1968–1980)

As explained in Section 2.6, it is expected that $M_S(\text{V})$ is systematically larger than M_S by about 0.19. It can be seen from Figure 4 that such a bias actually exists at least between M_S 7 and 8, and probably for M_S less than 7 [see also Abe (1981a)].

3.3.4 $m_b(\text{PDE})$ and $m_b(\text{ISC})$ (1964–1995)

Figure 5 shows that there are small systematic bias between these two magnitudes. This bias can be seen for both shallow and deep earthquakes. $m_b(\text{PDE})$ is about 0.05 higher than $m_b(\text{ISC})$ on the average. This difference persists from 1966 to 1997 (see Fig. 54 in the full manuscript on the attached Handbook CD, under the directory \44Utsu3). In the earliest two years (1964–65) the average difference is about 0.1. Here we use the notation m_b to represent $m_b(\text{PDE})$ or $m_b(\text{ISC}) + 0.05$. For large shallow earthquakes ($m_b > 6.4$) this difference seems to increase, though the data are rather few.

3.3.5 M_W and M_t (1901–1987)

The scale of M_t is so constructed that it gives the value equivalent to M_W (Abe, 1979a, 1989). Direct comparison between M_W and M_t in Figure 6 shows that there is no systematic difference between M_W and M_t except a few events that have special reasons for $M_t > M_W$.

3.4 Relationships between Two Magnitudes of Different Character

Here ten scattergrams are shown for five pairs of magnitudes together with the curves calculated from the master graph (Fig. 1). The remaining 20 scattergrams are included in the full manuscript on the attached Handbook CD, under the directory \44Utsu3.

3.4.1 M_W and $M_S(\text{V})$ (1977–1997)

The relation is shown in Figures 7 and 8. In general, the curve fits the plotted data well, but it yields somewhat large $M_S(\text{V})$ values for M_W less than about 6.

3.4.2 M_W and m_b (1977–1997)

The relation is shown in Figures 9 and 10 for all depths. The curve gives slightly large m_b values for $M_W >$ about 7.

3.4.3 $M_S(\text{V})$ and m_b (1968–1997)

The relation is shown in Figures 11 and 12. The curve fits the data for $M_S(\text{PDE})$ versus $m_b(\text{PDE})$. Slightly large $m_b(\text{ISC})$ values are obtained from the same curve.

3.4.4 M_W and M_J (1901–1997)

The relation is shown for shallow earthquakes (Fig. 13, $h < 100$ km) and deep earthquakes (Fig. 14, $h \geq 100$ km). It is seen that the M_W versus M_J curve fits well to shallow earthquakes, but does not fit for deep earthquakes. The difference $M_J - M_W$ tends to increase with depth (Katsumata, 1996). The M_J curve in Figure 1 should be applied to shallow earthquakes only.

3.4.5 $M_S(\text{V})$ and M_J (1968–1997)

This relation is shown in Figures 15 and 16. The M_S versus M_J curve fits $M_S(\text{PDE})$ data well, but some bias is seen for $M_S(\text{ISC})$ data. Although there are almost no systematic differences between $M_S(\text{PDE})$ and $M_S(\text{ISC})$ for the worldwide data (Fig. 3), some systematic difference of unknown origin exists for earthquakes in the vicinity of Japan as already pointed out by Utsu (1982b). The average difference $M_S(\text{PDE}) - M_S(\text{ISC})$ is 0.087 for Japanese earthquakes, whereas it is 0.019 for the worldwide data.

(Note: Additional relationships between two magnitudes of different character are given in the full manuscript on the attached Handbook CD, under the directory \44Utsu3.)

4. Comparison with Relations Proposed by Different Authors

Many papers have been published in which the relationships between two or more magnitude scales have been examined. The empirical relations obtained in these studies are usually represented by a linear equation like Eq. (1) in some limited range of magnitude. More discussions on magnitude-scale relationships have been given by Kárník (1973), Chung and Bernreuter (1981), Kanamori (1983), Nuttli (1983a), Heaton *et al.* (1986), Chen and Chen (1989), and Gusev (1991).

The equations reported in these papers representing the relationships between two magnitude scales, M_x and M_y , are plotted here in the form of $M_y - M_x$ versus M_x diagram. These are shown in Figures 17–22 (or Figs 43–48 in the full manuscript on the attached Handbook CD, under the directory \44Utsu3). The heavy lines in these diagrams represent the $M_y - M_x$ versus M_x curves derived from Figure 1. It can be seen that most of the heavy lines are located near the average position of the lines taken from various papers.

FIGURE 17 Relation between M_W ($\log M_0$) and M_S taken from 18 papers listed below. The thick curve indicates the relation shown in Figure 1. 1: Brune (1968), 2: Udías (1971), 3: Purcaru and Berckhemer (1978), 4: Singh and Havskov (1980), 5: Nuttli (1983b), 6: Dziewonski and Woodhouse (1983), 7: Nowroozi (1985), 8: Nuttli (1985), 9: Kiratzi *et al.* (1985), 10: Bergman (1986), 11: Ekström and Dziewonski (1988), 12: Chen and Chen (1989), 13: Main and Burton (1989, 1990), 14: Papazachos and Kiratzi (1992), 15: Johnston and Halchuk (1993), 16: Johnston (1996), 17: Giardini *et al.* (1997), 18: Pérez (1999).

Historical Seismicity and Tectonics: The Case of the Eastern Mediterranean and the Middle East

N.N. Ambraseys

Imperial College, London, United Kingdom

J.A. Jackson

University of Cambridge, Cambridge, United Kingdom

C.P. Melville

University of Cambridge, Cambridge, United Kingdom

1. Introduction

The purpose of this chapter is to describe how historical evidence can be used to address some fundamental questions: when and where have earthquakes happened in the past? Is the instrumental record of this century a guide to past seismicity, and sufficient to anticipate what might be expected in the future? How can accounts of ancient events contribute to our scientific understanding of earthquake activity? The discussion is drawn primarily from our studies of the seismicity and tectonics of the Eastern Mediterranean region and the Middle East (Fig. 1), and is based on our experience of research in this area over the last three decades. In this time, we have observed many problems in the use of historical evidence, but also considerable progress across the field. Our aim is to present a constructive statement of our views on a range of general points, rather than to engage in a detailed critique of individual cases.

As we cannot know what will happen in the future, to estimate likely earthquake hazards we have to find out what happened in the past and extrapolate from there. Previous research has uncovered evidence of destructive earthquakes in areas where only small events have been experienced recently (see for an early statement of this, Ambraseys, 1971). This is not surprising; the timescale of geology is vastly different from that of human history, so some areas will suffer a short period of violent earthquakes only once in a few hundred years. It follows that if we took account only of information about the last century, in which earthquakes have been recorded by instruments (and even then not uniformly throughout the globe), we would have no way of knowing

whether an apparently “quiet” area is in fact at risk from a damaging earthquake. The use of the historical record is invaluable, not only in the study of earthquakes but also of the climate and weather, and can guide the engineer to design

FIGURE 1 The area of our investigations, showing: (a) earthquakes of $m_b > 4$ during the period 1964–1990; (b) the distribution of significant shallow earthquakes this century. Open circles are M_S 6–6.9, solid circles are M_S 7.0 or greater.

structures to resist the forces of nature without being taken by surprise by unanticipated events.

Most of our information comes from local historians and chroniclers. For the better-documented regions where ancient civilizations and developed cultures have flourished, earthquake investigations can go back as far as the last 2500 y or so. Clearly, if such literary sources, which are written in both dead and living languages, are to be useful to modern science, the evidence they provide must be subjected to a rigorous critical analysis, informed by an awareness of the nature of the evidence they provide and of the context in which they were written. If these sources tell us enough about past earthquakes, we can, using modern techniques, estimate the size of these events and their likely effects should they happen again. In the same way, identifying the time intervals between destructive earthquakes in a certain place can help us to establish a pattern for their occurrence and the long-term seismicity in that area.

The use of long-term information, which can best be assessed from an interdisciplinary study, gives a far fuller understanding of earthquake hazard, because it is based on human experience of earthquakes over a much greater segment of the geological timescale, up to 2500 y or more in favorable conditions, than the mere 100 y of instrumental records. Fortunately, the region under consideration here is one of those that lends itself to such a long-term perspective. Similar work has been undertaken for other parts of Asia, such as China and Japan (see Gu Gongxu *et al.*, 1983; Utsu, 1990) and Europe (e.g., Alexandre, 1990; Stucchi, 1993; Albinì and Moroni, 1994). Such studies are essential in planning appropriate social and economic development to minimize the risk of unacceptable human and economic losses in areas of high seismicity.

2. Retrieval and Critical Review of Source Data

Historical information can be used to assess earthquake hazard, i.e., the frequency of occurrence of past earthquakes, in terms of their size and location, two of the most important factors in describing seismicity. But the results of historical studies will only be of value to engineers and earth scientists when the data are converted into numbers representing the epicentral location and magnitude of the events concerned, accompanied by an estimate of the reliability of the assessment (for discussions of the appropriate methodology, see, e.g., Ambraseys *et al.*, 1983; Melville, 1984; Guidoboni and Stucchi, 1993, and Chapter 47 by Guidoboni). It is sometimes helpful to divide the period studied on the basis of the sources at our disposal, as these naturally influence the quality of the conclusions that can be reached. The main division comes around the 15th century AD, obviously subject to different subdivisions in different parts of the region.

2.1 Early Period

The sources available for such a study in our area of research are of three main types: literary, epigraphic, and archaeological (cf., Guidoboni *et al.*, 1994; Ambraseys and White, 1997).

2.1.1 Literary Sources

So far as European sources are concerned, in contrast with the period after around 1400, for Classical, Roman, and Byzantine times almost all the sources are well known, relatively limited in number and mostly published. This makes it feasible to re-examine the original sources, rather than rely exclusively on modern catalogers, who may have been working from a variety of different standpoints (see below). The result should be a body of data that is homogeneous and as complete as possible, free of duplications and exaggerations, and therefore suitable for assessing seismicity with an accuracy adequate for scientific and applied purposes.

The main Arabic historical sources too, although relatively numerous in the “classical” age of Islamic civilization, that is from approximately the 8th to the 13th century AD, have generally been identified and published. These are for the most part narrative histories, usually arranged in annals, which report events in a precise chronological framework. The most significant events are frequently recorded, with characteristic details, by several authors. Critical comparisons of the various accounts are normally sufficient to identify and resolve small inconsistencies in dating, which have often found their way into modern earthquake catalogs (see, for one example, Ambraseys and Melville, 1988). Little or no archival material survives from this early period. Many works known to have been composed have not been discovered, but such information as they may have contained about earthquakes has very probably survived in the work of later annalists.

From the point of view of the seismologist or engineer, the principal justification for returning to the primary sources is to improve on previous interpretations, by adopting a consistent and systematic approach to all the pertinent earthquake reports. In so doing, of course, one is not simply looking to verify the information in existing catalogs. Applying a thorough knowledge of the material available for such studies, and of the history of the region investigated (which requires the appropriate specialist skills), has invariably allowed an enormous increase in data, not only for known but also for previously unknown events, in all properly conducted investigations over the last 20 y or so.

Naturally, for the analysis of seismotectonics, the prime purpose is not so much to investigate the historical implications of earthquakes for the social, political, and economic life of past centuries. Thus, historiographic and linguistic problems are relevant only when they have a direct bearing on the understanding of the earthquake(s) being described, for example by revealing any bias or unreliability in the author concerned, the quality of his information and the use he made

of the sources available to him. Purely historiographical research, interesting though it is, is ancillary in this context and is not the main end in itself.

2.1.2 Inscriptions

For some of the earliest events, information comes from inscriptions which explicitly mention earthquake destruction or extensive repairs after an earthquake. Epigraphic material may also refer to remission of tribute or taxes following an earthquake. The practice of inscribing such public proclamations on the walls of mosques in Iran, for example, is attested in the late 17th century and doubtless continued beyond that time, though no examples involving earthquakes are known. Since they are almost always contemporary, inscriptions provide valuable and indisputable evidence for the location and, quite often, the effects of earthquakes which, either because of the remoteness of the site, or for other reasons, are not recorded in literary sources. Following the same principle for epigraphy as for literary sources, excursions into linguistic or literary questions are only useful when they contribute to our understanding of the earthquake in question.

2.1.3 Archaeological Evidence

Great caution is needed in using archaeological data to locate and in particular to date earthquakes. Dating earthquake damage is frequently based on, or influenced by, literary sources (as filtered through earthquake catalogs) rather than any precise internal archaeological indicators. Stratigraphy alone, without some hard evidence such as coin finds, is insufficient to establish a chronological association between events that might have been entirely unrelated. The key point here is that the documentary record is grossly incomplete and numerous destructive earthquakes undoubtedly occurred of which no written description survives (see below). Nevertheless, in the past this has developed into a circular process, whereby the conclusions of archaeologists have been taken as factual evidence of earthquake activity and then used in turn by earthquake catalogs to confirm the dates of their entries.

Furthermore, the archaeological evidence for an earthquake is not always clear or unambiguous. Displaced, leaning, damaged, or collapsed walls in an excavation or in extant historical monuments are often explained by archaeologists as being due to an earthquake, invoked as a *deus ex machina* (cf. di Vita, 1995). But they can be due to other, nonseismic, causes such as differential settlements, particularly leaching or weathering of the foundation materials over the ages. This process of deterioration may indeed be assisted by occasional earthquakes, particularly when these structures have been rendered more vulnerable by acts of warfare. Random or coursed rubble masonry walls laid in clay mortar may deform excessively with time, even without the help of earthquakes, and originally badly aligned polygonal and rectangular dry walls can fracture owing to small differential settlements of

their lower courses, giving the impression of structural failure as a result of lateral or vertical inertia loading in an earthquake. Deliberate damage and military operations can also leave effects that may be misinterpreted. Furthermore, damage can be the result, perhaps cumulative, of more than one earthquake, even a long time after the abandonment of the site.

Much is often made of evidence from excavations and from the remains of historical monuments, that the ground motion at a given site during an earthquake was principally in the opposite direction to that of the collapse of free-standing walls and colonnades. This evidence is used to determine the attitude of postulated nearby surface faulting. But structures of the Classical, Roman, and early Byzantine period cannot fall easily in any direction other than that of their weaker axis. For colonnades, this is usually at about right angles to the long axis of the cella; for houses, perpendicular to the axis of the course of streets they face, regardless of whether there is a suspicion of seismic origin in their collapse or not. Prostrated colonades have been found in excavations not only near, but also far away from active faults in areas of both high and very low seismicity, such as for instance in Hermopolis Magna in Egypt. This mode of collapse has little to do with "the direction from which the shock came," a notion that has little engineering content. Also, the belief that the direction of fall is parallel with the direction of the near-field ground motion due to strike-slip surface faulting in an earthquake is not necessarily correct.

In recent years, considerable progress has been made in "archaeoseismology" and there is a greater awareness of the need for collaboration between archaeologists, geologists, and workers in other disciplines to evaluate the traces of earthquakes in excavations, both for understanding their effects at the site and for the information they can provide about the nature of the earthquake implicated (see, e.g., Guidoboni and Bianchi, 1995; Guidoboni, 1996; Stiros, 1996).

2.2 Later Period

For more recent periods, and for most areas, information becomes fuller and the sources of historical data more numerous as we approach modern times. Partly, this is a function of the greater survival rate of relevant documents. In the Middle East, the accumulation of material in conditions of relative political stability in great Ottoman imperial centers such as Cairo, Damascus, or Istanbul, greatly extends the opportunities for retrieval of "new" information from old records. Partly, also, it reflects the increased production of written material and, in the European context, the growth in literacy and secular learning associated particularly with the Renaissance. Commensurate with this is a broadening of the range of sources that may preserve accounts or details of earthquake activity.

Chronicles and annals remain the preponderant source of such data in Arabic works, in some areas (such as the Yemen) even well into the 20th century, supplemented only

occasionally by biographical, geographical, or topographical works. By contrast, European writings provide an ever-growing volume and range of data. Compilation of chronicles gives way to antiquarian study, travel literature, private diaries, personal letters and official archives, including diplomatic correspondence. By the 18th century in Europe and the 19th century in the Middle East, newspapers (the modern equivalent of the annals of old, in their indiscriminate reportage of ephemera, trivia, and the sensational alongside matters of serious material or moral concern) provide an accurately dated and reasonably full record of the newsworthy event (as differently perceived in different places and at different times). It is symptomatic of cultural changes since the World War I that, as instrumental, electronic or other mechanical reporting of events has grown, and news is increasingly disseminated by radio and television, a parallel decline is visible in both the volume and the quality of documentary and descriptive accounts of earthquakes in the 20th century.

Although such information allows considerable gains to be made, much material is still unpublished, often difficult to access and hard to read. There is no doubt that much remains to be discovered in Middle Eastern archive collections, particularly in Turkey and Egypt. Such work is time-consuming and presents serious hurdles (for a pertinent discussion, see Vogt, 1993). Nevertheless, pursuit of such data in recent decades has spawned a new generation of earthquake catalogs and studies of regional seismicity.

3. Existing Catalogs

Descriptive and parametric earthquakes catalogs are often accepted at face value by earth scientists and engineers and used to assess earthquake hazard. However, their results will necessarily only be as good as the input data. The reliability of these catalogs varies considerably and for the early period it can be very low (see Alexandre, 1990; Vogt 1993, 1996, with reference particularly to Europe, and discussion in Chapter 47 by Guidoboni).

There are many earthquake catalogs that cover the historical (pre-1900) period worldwide, but many of them are not well known outside Europe. Some of the main ones are therefore described briefly in Appendix 1.

There are many more parametric catalogs, which have appeared during the last two decades of electronic information. Though much useful work has been done, many of them are based largely on earlier catalogs and have the relatively modest aim of bringing previous lists up to date. In the process, it is easy for old and new copying errors to be introduced, which slowly accumulate and proliferate in various data-storage systems. If the limitations of these works are not fully appreciated, their use can create more problems than they resolve (cf. Guidoboni and Stucchi, 1993: 203).

The main touchstone for the value of any earthquake catalog is the extent to which it attempts to review primary source material and distil evidence of historical seismicity into a critical parametric form. Some of these modern catalogs are discussed in Appendix 2. There is insufficient space here to evaluate the aims and methods of each one, but earth scientists or engineers wishing to consult them should be aware of the need to judge the principles according to which they have been compiled and ensure that they are suitable for their purposes. It is best not to take any such material purely at face value; even the most rigorous catalogs are putting forward one interpretation of the available historical evidence and others are possible. Ideally, therefore, even the best modern catalogs are a starting point for an evaluation of hazard or seismotectonics in a particular area, appropriate to the specific concerns of the investigation.

As an example of the caution needed, Ambraseys and White (1996) found that by comparing original sources with those in earthquake catalogs used by historians and earth scientists for the whole period BC, of the 153 earthquakes listed, only 60% could be confirmed in the sources and the rest were more or less spurious. These figures do not much differ from those found by Alexandre (1990) for western European earthquakes for the period 394–1259 AD, where the percentage of spurious entries in catalogues varies between 50 and 75%. Similarly, in the case of Great Britain, of the 60 entries before 1620 listed in Davison's (1924) catalog, 25 (42%) can be shown to be either spurious or inaccurate. Of the 84 events in our study region listed for the last 500 y BC, 52 are dubious, leaving on average about six genuine historical earthquakes of all sizes per century. This is in contrast with 188 earthquakes of magnitude equal to or greater than 6.0 that have occurred in the same area during the last 100 y (Ambraseys and White, 1997).

Even without assuming an identical level of seismic activity throughout this long period, it is obvious that the number of earthquakes that can be retrieved from historical sources for the earliest historical past is minute, perhaps 3 out of 100, and demonstrates how many damaging earthquakes are missing from the literary record. This implies that the archeologist should not presume that what is identified as earthquake damage in an excavation is the effect of one of these very few known events, however well attested in the sources, rather than one of the many shocks missing from the record. The attractive and tidy tendency to assign damage to a known earthquake reminds one of Kaplan's parable of the drunkard searching under a street lamp for his house key, which he had dropped some distance away, but he searches there because there is more light.

For later periods, the situation improves, but many lists perpetuate "virus" events which are transmitted from catalog to catalog. A sample of inaccurate or spurious entries in lists for Egypt and the Red Sea region is given by Ambraseys *et al.* (1994: 107–110). Although many corrections lead to only

minor improvements in accuracy, it is inevitable that the largest events are the most frequently duplicated, because they are the most widely reported, and the duplication of such large earthquakes creates the most serious distortion of the record of seismotectonic activity. The problem is not the creation of modern authors, but is frequently inherent in the historical sources themselves. Sites may have been damaged or destroyed by separate events which occurred in the same week, month, or year, and for the very early period even in the same century, but not differentiated in contemporary accounts.

One instance of the various levels of problems that can surround a single event is provided by the large earthquake of 18 March 1068 in the Hejaz, which was reported to have caused damage between Jerusalem and Damascus, over 500 km from the epicentral region. In fact, it is probable that two separate events were involved. In addition to being two events reported as one, this large earthquake is duplicated under several dates in contemporary and secondary sources (see Ambraseys and Melville, 1989; Ambraseys *et al.*, 1994: 30–32). It is only recently that the reassessment of such early events is being undertaken in individual case studies or in the process of producing regional catalogs. Thus it is not surprising that many of the existing descriptive and parametric listings of past events attract rather negative criticisms in any critical review of historical seismicity (Vogt, 1996).

We may mention here four of the earliest earthquakes to which modern catalogers invariably give a cosmic dimension, the primary sources for which hardly support such an interpretation. The destruction of Sodom and Gomorrah in the Bible is probably associated with a distant and hazy recollection of ancient earthquakes in the Jordan Rift Valley sometime between 2100 and 1700 BC. The alleged earthquake destroyed Sodom and Gomorrah but not the nearby town of Zoar (Bible, Genesis: xix.24–30). According to a first-century AD source (Strabo: vii.297), the local inhabitants in his time said that "...there were once thirteen towns in the region of which Sodom was the metropolis, but that a circuit of about 60 stadia (11 km) of that town escaped unharmed; and that by reason of earthquakes and eruptions of fire... the lake burst its bounds... and, as for the towns, some were swallowed up and others were abandoned by such as were able to escape..." Sodom was probably located in the Lisan peninsula, on the east coast of the Dead Sea, not far from Zoar, which would appear from archaeological evidence to be in the vicinity of Bad el-Dra. The location of Gomorrah is not known with certainty. The earthquake should have been local, not necessarily of large magnitude, since, as we are told, destruction did not extend beyond a circuit of 60 stadia, which is less than 2 km radius. However, it seems that its catastrophic effects on these two towns were probably due to the massive liquefaction and slumping of the loose silty clays on which they were built (Harris and Beardow, 1995). It is difficult to see on what grounds this event is classed among the major events in this region (Ben-Menahem, 1991).

The second earthquake is another allegedly great event in Jericho in the Dead Sea Rift sometime between 1500 and 1200 BC. But the collapse of the walls of Jericho is not attributed by the Bible narrative, the only literary source that mentions the event, to a physical agency. Archaeological evidence (Kenyon, 1978) shows that between 1500 and 1200, Jericho had been damaged by one or more earthquakes, but there is no indication as to the date of these events, which may have nothing to do with the narrative in the Bible and which may even have happened since the abandonment of the site. The association of the event mentioned in the Bible with the damage preserved in the ruins of Jericho and in other sites in the region as well as with the damming of the Jordan river at Al Damieh is purely conjectural (see also, Nur and Ron, 1996).

A third catastrophic earthquake is alleged to have taken place circa 1365 BC in the Eastern Mediterranean. The evidence is a tablet from Tel Amarna in Egypt containing a report of the King of Tyre on the situation in Syria sent to Amenhotep-IV (1353–36) which says that "...Ugarit, the King's town, has been destroyed by fire; half the town has been burnt and the other half is no more..." The other half of the town was allegedly destroyed by a sea wave, alluded to in other, presumably contemporary, tablets (Dussaud, 1896; Virolleaud, 1935). However, those tablets that refer to the flooding of the land by the sea and also by the rivers, do not necessarily imply that the fire and the flood occurred at the same time, and they do not mention any destruction or association with an earthquake. Archaeological excavations of the Bronze Age site of Ugarit do reflect destruction of the city by earthquakes on several occasions (Schaeffer, 1939), but they provide no indication of seismic activity in this particular instance. It is perhaps significant that other contemporary and near-contemporary tablets that refer to Byblus on the Syrian coast about 160 km to the south of Ugarit, mention no destruction of the city by a sea wave or earthquake (Pomerance, 1970). The available evidence is too tenuous to support the claim put forward by modern writers (Dussaud, 1896; Schaeffer, 1939) that this was a "cosmic" earthquake that marked the end of the Late Bronze Age in this part of the eastern Mediterranean region (Schaeffer, 1948), or that it was the same event as that which destroyed Thera 1000 km away.

Finally, the earthquake of 21 July 365 was a relatively large earthquake, felt throughout the Eastern Mediterranean region, originating somewhere between Crete and the Peloponnese. It is mentioned by many contemporary and later authors, whose accounts, though sometimes confused, permit a reasonable idea of the main effects of the event. In Alexandria, thousands of houses were flooded and people were drowned. It is said that the anniversary of this inundation was commemorated by a yearly festival. The sea wave was reported also from other parts of the region. Along the Peloponnese, the Adriatic, and the Sicilian coasts its effects were more serious than those of the earthquake shaking itself. Indeed, judging by historical and archaeological evidence, ground shaking seems to have caused

damage only in southwest Greece, parts of Crete, and in Cyrenaica.

There is no reason to doubt that other regions were affected by this earthquake and its aftershocks, even though it seems improbable they were all destroyed or even damaged. The silence of contemporary and near-contemporary writers on the effects of this earthquake in Greece, Asia Minor, Egypt and in Central North Africa, undermines the case for the global nature of this event. It is relevant to note that not a single town named in historical sources suffered damage or destruction. Of the cities named in near-contemporary texts, Nicaea, Acreopolis and Germe can be shown to have been affected by different earthquakes in 362, 363, and 369 AD, respectively. In Antioch, the shock was felt, apparently without damage, and in Alexandria, as noticed above, it was clearly due to the seismic sea wave; as, indeed, was almost all the reported damage.

The earthquake is used as a point of reference for later writers, who add more sites where the 365 earthquake was allegedly destructive. The evidence is mainly drawn from archaeological observations, but with no clear indication of the simultaneity of the damaging effects in all these places. Inclusion of all these sites would imply an epicentral region extending from Gibraltar to the Dead Sea and from North Italy to northwest Turkey, clearly stretching the size of the event beyond the limits of the possible. Its most damaging effects were confined to a relatively small area, but one implying a magnitude in the upper 7.0s, probably nucleating at some depth, with a fault rupture breaking the surface and causing a substantial sea wave. The shock itself should have been felt across the Eastern Mediterranean, but associated with sporadic damage only to the most vulnerable structures outside this area. Indirect evidence, in need of authentication, suggests that the period 350–550 AD was perhaps one of the most seismically active periods in the region in the last two millennia (Pirazzoli, 1986). This may be so, but the 21 July 365 earthquake was not much different in size and effects from other large shocks in this part of the Eastern Mediterranean, such as those of 1303, 1508, 1609, 1856, and 1926 (see further, e.g., Jacques and Bosquet, 1984; Ambraseys *et al.*, 1994; Guidoboni *et al.*, 1994; Di Vita, 1995).

As in the case of the 365 event, quite often the amalgamation of the effects of two or more different earthquakes stretches the size of the event beyond the limits of the possible. How easily one might report two or more separate earthquakes as one, can be illustrated if we imagine the 20th-century seismicity of, say, Greece being transported back twenty centuries, and recorded in the terse manner typical of that period. The earthquakes of 20 April and 27 April 1894 in Martino and Atalante, for example, occurred so close together in time and space that, if not differentiated clearly in the sources, they could easily have been amalgamated by a later writer into a single major event (Ambraseys and Jackson, 1990). The chances of sources making such a fine distinction

in the past, when much information circulated orally and probably without great chronological precision, are slight.

In fact, despite assertions of simultaneity, historical sources rarely give sufficient evidence to establish this beyond doubt. The earthquakes of 1894 in our illustration had surface-wave magnitudes of 6.4 and 6.9, respectively. Their amalgamation, on the other hand, would produce a single major event of macroseismic magnitude well in excess of 7.5. This would seriously mislead the scientist faced with accommodating an earthquake of that magnitude into an area that is tectonically incapable of generating such large events. It is preferable, if in doubt, to report such events as separate earthquakes.

4. Assessment of Intensity Distribution and Isoseismal Maps

As early as the middle of the 18th century, investigators of earthquakes realized the usefulness of some kind of scale for the measurement of earthquake intensity at a given point. Since then, more than 60 different intensity scales have been devised worldwide, either to express the relative intensity of different earthquakes at a locality, or to trace the variation in intensity of a single earthquake over the affected area in the form of an isoseismal map. The latest scale proposed for Europe is the European Macroseismic Scale 1998 (Grunthal, 1998).

4.1 Intensity

Intensity is a convenient means of conveying (in a single rating of the scale) a measure of the effect of ground motion on artificial structures, and it is a useful parameter. Its assessment, however, in the upper range of the scale is subtle. It is often overlooked that by definition intensity is a rather vague measurement, either of the strength of the earthquake ground motion at a particular point, or the weakness of artificial structures and of the ground itself, or of both. Also, criteria based on secondary effects, such as landslides and faulting, are normally incorporated into the scale. It is impossible to assess how much or how little shaking is required to produce a slide, a type of ground failure that occurs more often without help from an earthquake than with it.

The rating of the upper grades of intensity, which describe damage (say over and above VI or VII), is regionally biased rather than regionally dependent. This is, first, because of regional differences in the geological environment or in the soil profile that may actually exist between different geographical regions or sites. Secondly, there are local, cultural differences in the predominant building stock that is exposed to an earthquake. A third bias lies in the limitations to the application of intensity scales, and the way they are interpreted by the seismologist and engineer, whether experienced or not.

Furthermore, authors of intensity data are seldom explicit about the system they have followed to arrive at their assessments.

Much of the rural and to a lesser extent urban building stock in southern Europe, the Middle East, and Central America is usually relatively old. It has already been weakened by previous earthquakes, by inadequate repairs and by aging, and subsists with an inbuilt vulnerability that is not accounted for in intensity scales. The result is that at intensities VII to VIII the scale “saturates;” that is, all houses are ruined or destroyed and any town or village would thus appear equally, but no more, devastated at so-called higher intensities.

The problem becomes more serious when we consider the assessment of large epicentral intensities, when any scale becomes too subjective and potentially misleading, particularly if it has been designed to describe conditions in a different part of the world, or includes ground effects such as landslides or faulting as diagnostics. A comparison of epicentral intensities assessed independently by different investigators of the same event can show unacceptable differences, up to two grades or more, particularly when intensities are assessed from questionnaires and press reports, without visiting the region, or from the maximum reported intensity and not the mode of the observed estimates. Such a comparison shows how sensitive the method is to the experience of the investigator and the means and time at his or her disposal (see further, Ambraseys and Melville, 1982: 30).

All these problems occur because the description of intensity scale ratings is not precise enough and damage is not consistent enough to do otherwise. In addition, intensities are often assessed by inexperienced observers, “arm-chair” seismologists, and earthquake engineers. It is immaterial, therefore, how precisely one cares to treat the intensity values at one’s disposal, since large uncertainties in their original assessment must always exist; in many cases these are so large that their correlation with other measured and more reliably determined earthquake parameters contaminates the final results.

The most recent EMS-1998 intensity scale (Grunthal, 1998) is an attempt to overcome some of these difficulties, but this does not alter the fact that all our existing intensity data come from earlier scales and events. Furthermore, the EMS-1998 scale is too idealized and cumbersome to use in practice. Under the circumstances, one is inclined to sympathize with users of these earlier scales; inasmuch as we are not in a position to be rigorous in our definition of various ratings, then the experienced investigator should have enough leeway to use his or her own judgment without being hemmed in by a scale that is too rigorous or specific.

4.2 Correlation of Intensity with Ground Motions

The practical problem with intensity begins when the engineer, with little hesitation and perhaps with even less understanding

of the subtleties involved in its definition and assessment, adopts intensity as a means for the calculation of ground acceleration for design purposes.

In most of the attempts made in the past to correlate intensity with peak ground acceleration, the enormous scatter of data clearly shows, as it should, that there is no physical justification for such a one-to-one relationship (see for instance, Hersberger, 1956; Ambraseys, 1973). The conversion of intensity into peak ground acceleration may be used by the engineer as a last resort, but this must be done at his own risk and with the understanding that such conversion formulas have an enormous scatter and low confidence levels. It is simply not sufficient to derive such correlations without at the same time being explicit about the uncertainties involved.

The prevailing tendency to rely on intensity values to derive empirical relations between intensity and maximum ground acceleration, or between epicentral intensity and magnitude, is rather disappointing. In most scales, sites in the immediate vicinity of a coseismic surface fault-break are assigned epicentral intensities of IX or greater, a value for which empirical formulas predict a magnitude greater than 7.0. In general, the presence or absence of a coseismic surface break is independent of magnitude, though it is rare below about $M=5.5$. It would be preferable not to make assumptions that are not testable nor to advocate on the basis of inadequate physical evidence.

4.3 Isoseismal Maps

Like other empirical measures, intensity, with all the uncertainties in its estimation, when assessed for an earthquake at a large number of points and drawn as an isoseismal map, shows regular distribution patterns and dimensions of the felt area. These indicators have in the past helped seismologists to estimate the size and relative depth of an event.

An isoseismal map provides a measure of the size of the areas over which an earthquake was felt at different intensities; this is an indirect measure of the magnitude or the energy released by the event. The magnitude of an earthquake, therefore, may be assessed from the size of the areas over which a shock was felt, which can then be calibrated against macroseismic information about similar, 20th-century earthquakes for which reliable instrumental magnitudes are available. Such calibration relations may be used to assess the magnitude of historical events for which isoseismal maps can be drawn.

Thus, although intensity at a given point tells the engineer little about ground motion, isoseismal maps, in the construction of which intensity estimates undergo a significant amount of averaging and smoothing of inherent bias, provide a useful tool with which to assess magnitude. Felt areas or average isoseismal radii may be used in calibration relations to estimate magnitude, from which the zero period or spectral ordinates of ground motion can be estimated using modern

procedures. In this way ground motions are approached via magnitude and not directly via local Intensity (Howell and Schultz, 1975; Ambraseys, 1985).

It is important, therefore, that isoseismal maps for correlation with magnitude are uniformly drawn and are not regionally biased, which is not always the case. For instance, in the annual US earthquake publications for the period 1929–1969, isoseismal maps were prepared by different staff members of the US Coast and Geodetic Survey from a listing of small towns or suburbs all having the same intensity. The maps were prepared, as was then the custom, by assuming that if in a small town or suburb the intensity varied through a range of values, the highest value was used for the whole area rather than the mode of the observations. In contrast, Russian practice was to use the mode of intensity ratings observed within a particular area.

Regional bias also has an effect on intensity attenuation laws, and is influenced by the personnel responsible for drawing national intensity maps or the agencies involved in their preparation. This becomes apparent with earthquakes affecting more than one country, where individual intensity maps prepared separately for each country frequently do not match across national borders, mismatching by as much as three intensity ratings (Ambraseys and Moinfar, 1988).

5. Assessment of the Size of Early Events

In spite of what has been said earlier about intensities, there is a simple and logical approach to making good use of intensity to assess the size of a shallow earthquake and to discriminate between shallow and intermediate depth events, important considerations in the study of historical events.

The size of a modern or historical earthquake can be assessed reasonably well from the correlation of its “felt radius,” that is, the radius of the area within which the shock was felt with a low intensity, say III to IV, with its instrumental surface-wave magnitude. Free-field low intensities are not affected by the regional vulnerability of human-made structures.

Such correlations may be used to assess the surface-wave magnitude of historical events from the size of their felt area. They should be derived from reliable 20th-century macroseismic data and from uniformly assessed surface-wave magnitudes, M_S , using an orthogonal regression technique from which uncertainties in predicted estimates and depth are also determined.

For the preinstrumental period, M_S can be assessed using calibration formulas which can be derived from regional, shallow, 20th-century earthquakes in terms of their radii of isoseismals, r_i , and corresponding intensities, I_i , in the MSK (Medvedev, Sponheuer, Karnik) scale. For our region, the

calibration formula used was derived from 123 shallow ($h < 26$ km) earthquakes in the region between 1905 and 1990, and from their corresponding M_S values, which have been recalculated uniformly. The predictive relationship, is

$$M_S = -1.54 + 0.65(I_i) + 0.0029(R_i) + 2.14 \log(R_i) + 0.32p \quad (1)$$

where $R_i = (r_i^2 + 9.7^2)^{0.5}$ and r_i , in kilometers, is the mean isoseismal radius of intensity I_i ; p is zero for mean values and one for 84 percentile values.

6. Coseismic Surface Faulting Associated with Historical Events

Evidence for coseismic surface faulting in historical earthquakes in the Eastern Mediterranean and the Middle East is of importance to all modern studies of tectonics and seismicity. Such evidence not only confirms that known tectonic structures are active, but can also identify new ones. Despite shortcomings in the documentary evidence, information about surface faulting can be found in contemporary accounts and this provides a valuable reference point in the paleoseismological record of faults. Such knowledge is particularly important when, for example, the activity of a fault is to be researched by trenching methods, as it allows the completeness of the paleoseismological investigation to be assessed.

Obviously, the most interesting cases of faulting are those that could not have been predicted from the record of 20th-century seismicity alone or, conversely, where surface faulting could be expected but until now is not known to have occurred.

The area we investigated for this reason is within latitude 25 and 45° N and longitude 18 and 70° E (Fig. 2). It comprises the Balkans, Turkey, the Caucasus and the Middle East up to west Pakistan, a region of active tectonics and with a history which is amply, but not uniformly, documented throughout the past two millennia (Ambraseys and Jackson, 1998). Such information is particularly important for studies of active tectonics and for paleoseismology.

We have found 78 cases of faulting pre-1900 and 72 post-1900. Table 1 presents all the cases of pre-1900 coseismic surface faulting known to us at present, which shows that faults which appear to be quiescent today have been active more than once in historical times, as well as a number of hitherto unknown active faults. A few of these cases are also included in the works of Wells and Coppersmith (1994) and Yeates *et al.* (1996). Comparison with the post-1900 record shows that in some cases, a recurrence of historical faulting has not been observed during the instrumental period.

The data are sufficient to allow the derivation of relationships between magnitude and rupture length.

FIGURE 2 (a) The locations of all earthquakes thought to be associated with coseismic surface faulting for the whole period of observations; (b) the locations of pre-20th century earthquakes thought to be associated with coseismic surface faulting; (c) 20th-century earthquakes associated with coseismic surface faulting.

Historical sources record large surface fault ruptures, small ruptures not being spectacular enough to attract attention. Descriptions from which one can deduce faulting are relatively few and hard to verify, particularly when the sources are secondary and the recorded ground deformations are not well described (see, e.g., Ambraseys and Melville, 1995). One of the problems in both early and later descriptions of surface faulting is that one cannot always be certain as to whether ground deformations associated with an earthquake were of tectonic origin or due to landslides, liquefaction, or slumping of the ground. In some cases, ground deformations genuinely of tectonic origin can be identified from the description of ground ruptures which extended continuously or discontinuously along considerable distances, but relative displacements are seldom given for vertical, and never for horizontal, slip. The information which is usually available for this period, therefore, may be

classified into three broad categories according to the following criteria.

1. Strong evidence for surface faulting explicitly (A) or implicitly (a) described in the sources. The length of the rupture is rarely given, and only in few cases can it be reckoned from the distances between the localities which it traversed.
2. Surface faulting that is not supported by clear evidence can be inferred from the alignment of a long and narrow epicentral region of a large magnitude earthquake close to or along a known fault. Occasionally the length of a break can be reckoned from the length of the long axis of the epicentral region which contains an assumed rupture. Clearly this would not tell us exactly how far the fault-rupture extended, but would suggest that the shock was probably associated with a surface rupture that can be investigated today in the field. In these cases, historical information will not reveal the exact location and rupture length, but it can help to define the time and the segment of the zone that was probably ruptured.
3. Faulting assumed because of the large size ($M_S > 7.0$) of the associated earthquake and its proximity to a known active fault zone. This category is more tenuous than category 2, but was included to guide further studies. There are many events of $M_S > 7.0$ that might have been associated with faulting, such as those in and around the Marmara Sea area, in Eastern Anatolia and Iran, but these are omitted as their epicentral area is ill defined.

Of these three categories, (1) involves some ruptures which may not previously have been associated with known active or Quaternary faults. Categories (2) and (3) merely date probable breaks of segments of known faults, and help assign size to these events. All these cases indicate recent activity, because the proximity of these earthquakes to known faults was part of the evidence assigning them to these categories.

During the instrumental period, information about both the faulting and the seismological parameters of the associated earthquake improves; there are more detailed field observations and better instrumental data, allowing the uniform re-assessment of instrumental M_S magnitudes. However, during the first half of the 20th century, this improvement was very slow and surface faulting continued to be imperfectly reported. Occasionally surface fault ruptures were attributed to landslides and slumping of the ground, and preexisting Quaternary fault scarps were often associated with recent earthquakes.

In this investigation it is important to know the magnitude of the causative earthquake, not only for the development of predictive moment-magnitude relations as a function of the length, slip, and attitude, but also for hazard analysis. For the preinstrumental period, surface-wave magnitudes, M_S , can be assessed from Eq. (1). For the late, preinstrumental period, macroseismic data improve in quality and quantity and this allows the use of Eq. (1) for the assessment of magnitudes.

All events are assumed to be crustal.

^aMagnitude: Magnitudes have been derived from macroseismic information calibrated against 20th century instrumental M_S values. The size of historical events under investigation has been classified under three broad categories: V: very large event $M_S > 8.0$; L: large event $7.0 < M_S < 8.0$; M: medium event $6.0 < M_S < 7.0$.

^bFault attitude and mechanism: T = thrust; L = left lateral strike slip; R = right lateral strike slip; N = normal, with a combination of these symbols for oblique motion; * = assumed from regional pattern.

^cLength of faulting: L = total length of surface rupture, including intermediate unfractured segments in km.

^dRelative displacements: H = maximum observed lateral offset in cm; V = maximum observed vertical offset in cm; S = indicates small displacements of imperceptible sense of motion; – = no data.

^eQuality of evidence of faulting Q (first column for Q): A, surface faulting explicitly or (a) implicitly, deduced from the sources or field investigations; B, no evidence for faulting in the sources; surface faulting inferred from the elongated shape of the epicentral region; C, faulting assumed because of the large size of the earthquake and its proximity to a known active fault zone.

^fLocation evidence (second column for Q) for quality categories A and a, is subdivided into: G = good, derived from detailed field studies; M = moderate, based on cursory field survey of the fracture zone; P = poor, deduced from historical data or, for more recent events from field evidence in need of authentication; A = very poor, exact location of fault-break not known.

^gNature of fault zone (third column for Q): d = trace discontinuous or eroded; total length of rupture deduced from few and widely spaced reported observations; U = arcuate trace, graben, or complex fault zone; k = some of the observed or reported ground deformations probably not of tectonic origin; i = only part of the break was accessible or mapped; actual rupture length is probably longer than reported; n = reported ground effects, to the best of our judgment, not of tectonic origin, or associated with a known earthquake; m = multiple shock; observed deformations and rupture length probably enhanced by more than one earthquake.

^hFor quality A, B and C (in any column of Q): f = assumed association of historical event with known Quaternary or recent fault-break.

ⁱThe name of the location where the event took place is given in the penultimate column, and the last column gives the country: AF, Afghanistan; AL, Albania; BU, Bulgaria; GR, Greece; IQ, Iraq; IR, Iran; IS, Israel; LE, Lebanon; MC, Macedonia; PK, Pakistan; SA, Saudi Arabia; SY, Syria; TR, Turkey; TU, Turkmenistan.

For 62 of the 150 cases of surface faulting retrieved we have both well-determined surface-wave magnitudes from instrumental data, and reasonably reliable rupture lengths from field observations. These events are all in the instrumental period, with 55% of the data coming from strike-slip, 30% from normal and 15% from thrust faults, excluding cases of quality (2) and others for which the rupture length is imperfectly known.

A straightforward orthogonal regression between M_S and $\log(L)$ gives:

$$M_S = 5.13 + 1.14 \log(L) \quad (2)$$

with L in kilometers, with a standard deviation of 0.15 in M_S . Alternatively, regressions of M_S on $\log(L)$, and of $\log(L)$ on

M_S give

$$M_S = 5.27 + 1.04 \log(L) \quad (3)$$

and

$$\log(L) = -4.09 + 0.82 M_S \quad (4)$$

respectively, with almost the same standard deviation of 0.22 in M_S for both cases, whereas a nonlinear fit results in

$$M_S = 5.06 + 1.42 \log(L) - 0.14 [\log(L)]^2 \quad (5)$$

with a slightly larger standard deviation (see Ambraseys and Jackson, 1998).

For 58 of the 62 earthquakes used to derive Eqs. (2)–(5) we have also horizontal (H) and vertical (V) maximum surface displacements but the fit improves little, given by

$$M_S = 5.11 + 0.86 \log(L) + 0.21 \log(R) \quad (6)$$

with a standard deviation of 0.20 in M_S , in which R is the resultant displacement from H and V , in centimeters.

In terms of resultant displacement R alone, M_S may be approximated by

$$M_S = 5.21 + 0.78 \log(R) \quad (7)$$

with a rather large standard deviation of 0.36 in M_S .

We find that the resultant displacement R is about $5.0 (\pm 4.0) \times 10^{-5} L$, regardless of mechanism. This value for R is no surprise, and is similar to that found in global compilations of more modern datasets (e.g., Scholz, 1982). However, the size of the sample is insufficient and the scatter too large to allow a better estimate of R as a function of mechanism.

However, it is important, particularly for paleoseismological investigations, to have some indication of whether the rupture length and offset estimated from historical sources are likely to be seriously under- or overestimated, given the magnitude of the event or vice versa. This is a principal use of magnitude–length relationships. For an assessment of individual events or particular regions, it may be more informative to make such estimates from a combination of first principles and more closely constrained empirical relationships, along the following lines (Ambraseys and Jackson, 1998).

1. For earthquakes that rupture the entire thickness (d) of the seismogenic upper crust, the down-dip width of the fault is $d/\sin \theta$, where θ is the fault dip, and the moment is then

$$M_0 = (mcd/\sin \theta)L^2 \quad (8)$$

where m is the rigidity modulus and c is the ratio of average displacement (u) to fault length (L), which is

observed to be close to $5 \times 10^{-5} L$ for intracontinental earthquakes (Scholz, 1982).

2. Both observationally and theoretically it is known that for such earthquakes the relationship between moment and magnitude (M , where M_S or M_W) is of the form

$$\log(M_0) = A + BM \quad (9)$$

where A and B are constants, with $B = 1.5$ for events with M not smaller than about 6.0.

3. Combining these expressions gives a relationship between moment and fault length of the form

$$M_0 = \log(mcd/\sin \theta)/B - A/B + 2(\log L)/B \quad (10)$$

For illustration, if we take $m = 3 \times 10^{-3} \text{ Nm}^{-2}$, $c = 5 \times 10^{-5}$ and $B = 1.5$, then for a seismogenic layer of thickness $d = 15 \text{ km}$ and vertical strike-slip fault ($\theta = 90^\circ$) the relationship is

$$M_W \text{ or } M_S = 4.9 + 1.33 \log(L) \quad (11)$$

with L in kilometers, which is similar to the empirical relationship [Eq. (2)].

7. Discussion

The reappraisal of the seismicity of the Eastern Mediterranean and the Middle East, east of the Adriatic and the Ionian Seas all the way to Pakistan, shows that although the historical record is incomplete, careful reading of the available data can provide valuable insights into the long-term seismicity of the region. The pattern of seismic activity of many areas is seen to have changed little over the past 2500 y, whereas other areas that are at present quiescent can be shown to be capable of generating earthquakes of significant size. The following are some of the lessons we believe we have learned from these studies.

- Archaeological evidence for an earthquake is not always unambiguous and can seldom be used to provide a precise date for the damage caused. Nevertheless, archaeological evidence can provide confirmation of long-term seismicity in a given region and with greater collaboration between disciplines it is likely that many refinements of the existing database will be possible.
- For the earth scientist and earthquake engineer the main objectives of historical research into primary sources are to refine and extend the information contained in secondary studies and catalogs, and to provide an objective measure of the reliability and completeness of the data retrieved.
- It is important to establish unambiguously the simultaneity of damage to different localities in a historical

earthquake. Often one finds cases in which two separate events have been transformed into a large earthquake. This is understandable in view of the tendency of both contemporary and later writers to amalgamate seismic events, whether for lack of sufficiently precise information, from ignorance of the true nature of earthquakes, or from simple convenience. Such an amalgamation of effects will overestimate the size of the damage area, and hence of the size of the event.

- Although some of the problems of dating can be resolved, it is often more difficult to determine a sufficiently accurate location for historical earthquakes. The epicentral area of an historical event is not always certain and judgment has to be exercised to ascertain its location. The primary aim should be to avoid both the amalgamation and duplication of events.
- The size of an historical earthquake can be assessed in terms of its magnitude; such an assessment for historical events can be made only approximately and depends on the reliability of information regarding their effects at large epicentral distances or from the dimensions of their epicentral area. For events in which this information could be estimated, the magnitude of the event should be estimated using a calibration formula derived from 20th-century earthquakes for the region.
- In estimating intensities we find that at large distances an earthquake may cause the collapse of a few important but vulnerable constructions, for which there may be archaeological or historical evidence. This information alone should not always be taken to mean that all the other human-made structures at these sites have been destroyed. The observed effects can be the result of the high vulnerability of long-period structures to sustained ground motions, rather than of the severity of the shock.
- For many historical events, the data are wholly insufficient to permit assessment of intensity in terms of any of the scales currently in use, let alone to reckon the magnitude of an event, except in very general terms. We find that precise local or epicentral intensities assigned by modern catalogers to many historical events, particularly in Greece and the Holy Land, are hypothetical and often inflated.
- Earthquake catalogs are often used by earth scientists and engineers to assess earthquake hazard. A more critical attitude is needed to rely only on those that combine the interpretation of primary sources with estimates of the reliability and completeness of the data provided.
- The location and size of historical earthquakes should not be used for scientific purposes without proper scrutiny of the associated historical material.
- The historical record confirms that some regions that are active today (e.g., the north Anatolian fault zone) were also active 2500 y ago, demonstrating the long-term nature of their seismicity. It also shows that some regions

that are at present quiescent (such as the Jordan Rift Valley), are capable of generating relatively large earthquakes. For some of these events this is consistent with their known active tectonic environment.

- Too many modern catalogs of historical seismicity are not sufficiently rigorous to be treated with confidence. This has often been due to the interdisciplinary nature of this field of study, which requires scientists to examine literary texts and historians to glean scientific information from their sources. The result has been the production of a large number of false earthquakes, or of seismic events of a size beyond the limits of the possible, often with a sensationalist tinge. This is of no technical consequence, provided the Earth-scientist and engineer are aware of it.

In view of the uneven value of parametric catalogs that are not based on a reassessment of primary source data, it is important that principles of interpretation should be laid down for the benefit of those working in historical seismicity, since this kind of work will be of value to engineers and other scientists only when the results are reasonably reliable and capable of being converted into figures.

Appendix 1. Historical Earthquake Catalogs

Manetti's work (in late Latin) is the earliest-known compendium of earthquakes and contains an annotated list of earthquakes in the Eastern Mediterranean and elsewhere up to 1456. Manetti does not always cite his sources and quite often the year of an earthquake is recorded only by reference to other events.

Al-Suyut's earthquake catalog (in Arabic) was compiled in the early part of the 16th century and extended by his continuators to the year 1588. It is a reliable source of information for the Muslim world, covering the region from Morocco to Transoxania.

Bonito's large world earthquake catalog (in Italian) is an invaluable compendium of information about earthquakes that ends with 1690. Its 822 pages contain a wealth of information culled from a variety of sources, which Bonito quotes and occasionally annotates. His work provides an excellent starting point for the identification of earthquakes in Europe and in the New World (Bonito, 1691).

Coronelli's work (in old Italian), although prepared as a global catalog of earthquakes up to 1693, deals mainly with events in the central and eastern Mediterranean. Annotations are kept very brief, making no reference to sources of information and occasionally neglecting to give the full date of an event (Coronelli, 1693).

An anonymous compilation of earthquakes throughout the world was published (in German) in a series of issues of the *Dressdenische Gelehrte Anzeigen* in 1756, and is a useful

source of information for earthquakes worldwide during the 16th and 17th centuries up to 1691 (PDGA, 1756).

Hoff's general catalogue of earthquakes (in German) is a valuable work, covering events worldwide for the period up to the end of the 17th century. It is an accurate and methodical study, drawing on a variety of published sources, which are cited (Hoff, 1840).

The compilation of Seyfart's work (in German) on earthquakes was prompted, like many similar works of the mid-18th century, by the large Lisbon earthquake of 1755. It contains interesting entries, mostly extracted from published material in Europe, such as flysheets and newsletters, as well as from the European press (Seyfart, 1756).

Berryat's long chronological list (in French) is an annotated collection of information about earthquakes up to 1760. The author does not cite his sources but they seem to include, among others, earlier catalogs and information from the European press (Berryat, 1761).

Hoff compiled twelve annual earthquake catalogues (in German) for the years 1821–32. He extracted much of the information from press reports, travel diaries and from correspondence. His work is of interest for areas outside Europe (Hoff, 1826–35, 1840–41).

Mallet's catalog occupies nearly 600 pages and contains almost 7000 events worldwide. Although based on several earlier catalogs, especially on those of Hoff and Perrey, his catalog for the period after the 17th century contains a considerable amount of information from relatively early press reports, some of which are useful for investigating the seismicity of the Americas and the Far East (Mallet, 1850–58).

Perrey's annual lists of earthquakes (in French) for the 29 years 1843–71 are invaluable. They occupy 28 papers and the total number of pages in these *Mémoires* is just over 2500. Perrey collected much of the material by correspondence and also from the international press. His annual lists are a vast storehouse of facts; for the most part he was content to leave discussion of the results to others. There is seldom any attempt to determine the position of the epicenter, none to discover the relation between mainshock and aftershocks or the relation between shocks felt at the same time at different places (Perrey, 1848–75).

Schmidt's catalogs (in German) for the Southern Balkans and Asia Minor is one of the most important sets of data for the region. It depends very little on previous lists or catalogs and from about 1800 onwards, is the result of his own labors. From after about 1858 to the end of 1878, his catalogue contains just under 4000 entries, derived chiefly from correspondence with observers, travelers, and consuls throughout the Eastern Mediterranean and from the Press in Athens, Istanbul, Izmir, and other places in the area (Schmidt, 1867, 1879).

A long memoir (in German) containing lists of earthquakes for the twenty years, 1865–84, was published by Fuchs. These lists include nearly 10 000 entries altogether, containing

a substantial amount of information for earthquakes worldwide. In common with some other catalogs, this work must be used with caution, for nowhere does Fuchs cite his sources, and it is accordingly difficult now to appreciate the value of the information that he retrieved (Fuchs, 1886).

Musketoff and Orloff's earthquake catalog (in Russian) for the Russian empire ends in 1888. It is based on previous catalogs but also on contemporary national and local Russian press reports and to a lesser extent on unpublished documents. Events are fully annotated and sources are given in full. This is a very useful source of information (Musketoff and Orloff, 1891).

Appendix 2. Modern Catalogs

Milne's world catalogue of destructive earthquakes up to 1899 is based entirely on previous lists. It is devoid of information from original sources (Milne, 1911).

Montessus de Ballore's world catalog (in French), containing 171 434 entries, covers the period up to 1906. Only a small fraction of this enormous volume of information, which covers mainly the second half of the 19th century, has been published, and it remains little known. However, the published information is not of very great value; the unpublished files, kept in the Department des Cartes et Plans, Depot de la Société de Géographie of the Bibliothèque Nationale in Paris, where they occupy 30 m of bookshelf, did not prove, on examination, to be as useful as had been anticipated. Much of the information in these files was extracted from previous catalogs and press reports, with little original material derived from correspondence with observers (Ballore, 1900, 1905, 1924).

Sieberg's annotated world catalog of earthquakes (in German) contains a considerable amount of information, including isoseismal maps for the larger historical earthquakes worldwide up to 1930. However, this catalog gives little indication of his sources of information and contains many errors and duplications in entries. Nevertheless, this highly inaccurate work has for many years been regarded as a standard reference on the subject (Sieberg, 1932a,b).

Stepanian's annotated catalogs (in Russian and Armenian) of earthquakes in Greater Armenia are a useful set of documents. They are based on a considerable number of primary published Armenian sources. These Armenian catalogs of Stepanian are little known; they are accurate and methodical, and contain about 800 events (Stepanian, 1942, 1964). Subsequent work by Guidoboni and Traina (1995) has brought this up to date.

Byus' catalog of earthquakes in the Caucasus and adjacent regions (in Russian) is a systematic compilation of information from previous catalogs, in some cases critically selected, as well as from local Georgian, Armenian, and Russian sources, including local newspapers and reports. This 600-page work contains a wealth of information about events in the Middle East (Byus, 1948).

Rethly's compilation of earthquakes in the Carpathian region and central Europe (in Hungarian) is a serious piece of work. It contains extracts from original sources and is fully referenced. This work is invaluable for the identification of events that affected southeast Europe (Rethly, 1952).

The survey of the seismicity of the Balkan region carried out by UNESCO in the mid-1970s, contributed a summary of the material available at that time for the assessment of regional seismicity. Iseismal maps for a few events before 1900 and a parametric catalog were published, but must now be used with caution (Shebalin *et al.*, 1974).

The catalogs of earthquakes in the Middle East and along the Dead Sea Rift by Ben-Menahem (1979, 1991) contain information extracted from earlier catalogs of varying quality and from secondary works. These lists, which include a parametric catalog going back to 2050 BC, must be used with caution.

The national earthquake catalog of the former USSR (in Russian) covers a large geographical area for the period before 1977 (Kondorskaya and Shebalin, 1982). It is based chiefly on secondary macroseismic sources but includes a detailed procedure for the systematic quantification of historical events in the region.

The catalog of Poirier and Taher (1980), covers the seismicity of the Middle East, listing nearly 200 events up to 1800. It summarizes information taken from a thorough survey of Arabic source material, presented in Taher's doctoral thesis, Sorbonne, 1979. References are properly identified and cited. Though the catalog contains various errors and duplications, this is a considerable improvement on earlier work. A more extended summary of these primary data, although regrettably without any reference to modern studies of the last two decades, is currently in progress (Taher, 1996).

A useful catalog by Russell (1985) for Palestine in the period to the mid-8th century, presents the texts of the accounts of earthquakes in the region from contemporary sources and attempts to resolve discrepancies in dating. The catalog also provides archaeological evidence of damage that has been adduced to support the dating of some of these events, or to be dated by them.

The works by Ambraseys and Melville (1982) and Ambraseys *et al.* (1994) attempt a thorough re-evaluation of the long-term seismicity of Iran, Saudi Arabia, and the Red Sea, based as far as possible on primary sources. These works present in some detail the methodology proposed to assess historical seismicity by combining instrumental data and macroseismic information.

An authoritative compilation of primary sources for earthquakes in Italy and in the eastern Mediterranean (Guidoboni, 1989; Guidoboni *et al.*, 1994) covers the period from the 8th century BC to 1000 AD. Events are annotated in detail and sources are quoted in full. There is no attempt to determine epicentral areas or to assess the size of the events it describes.

The work by Ambraseys and Finkel (1995) covers Turkey and parts of the Middle East for the period from 1500 to 1800 and is based chiefly on unpublished sources of information.

The catalogs of Papazachos and Papazachou (1989 in Greek, 1997) cover the historical seismicity of Greece and adjacent regions. These are annotated compilations based essentially on previous catalogs.

The work (in Greek) by Spyropoulos (1997) is an exhaustive annotated corpus of extracts from original sources relating to historical earthquakes in Greece.

Earthquakes and Archaeology

Amos Nur

Stanford University, Stanford, USA

1. Introduction

Although earthquakes have often been associated with unexplained past societal disasters, their impact has been thought to be only secondary for two reasons: inconclusive archaeological interpretation of excavated destruction, and misconceptions about patterns of seismicity. However, new and revised archaeological evidence and a better understanding of the irregularities of the time–space patterns of large earthquakes together suggest that earthquakes have played a role, and at times a key role, in shaping the history of mankind in Central America, Peru, the southwestern USA, China, Japan, and the Eastern Mediterranean.

The Eastern Mediterranean region is one of the most actively excavated areas in the world of archaeology. Many sites in this region are in the form of “Tels” – large, flat-topped, largely artificial mounds, composed of the accumulated layers of collapsed human habitation. Many archaeologists and historians tend to attribute the widespread destructions found in many of these excavations to the actions of man at war and time. However, since this region is also a region of earthquake activity, it is inescapable that earthquakes and archaeology could be intimately related. It is only recently (Stiros and Jones, 1996) that earth scientists and archaeologists have come together to formally address the evidence for earthquakes and their significance in archaeological remains (Nur *et al.*, 1991; Guidoboni, 1994; Nur and Ron, 1996; Nur and Cline, 2000), and resolve the disagreements over the role earthquakes could have played in ancient society.

2. Earthquakes in Human History: Some Examples

Earthquakes have accompanied humans since the beginning of time. However, the time between large earthquakes is usually longer than one generation, often more on the order of ten generations. Thus most people have no personal experience with earthquakes, and they do not factor the possibility of earthquakes into their everyday lives, even if they know

intellectually that they live in an earthquake hazard area. It is therefore sometimes hard to appreciate that major earthquake catastrophes are natural facts that have affected people since the dawn of human time. A few examples are described in the following sections.

2.1 Ubeidiya

The oldest human-made structure we know on Earth is found in Ubeidiya, Israel (Bar-Yosef, 1993), a little gully inside a small pull apart basin right on the Dead Sea transform fault south of the Sea of Galilee and near the River Jordan. The “structure” is the simplest possible—a flat floor made of pebbles—that was put there around 1–1.5 Ma by the appropriately named “Pebble Man.” Apparently, these humanoids made the floor by pressing small river pebbles into the muddy bank on the Jordan. Thus, instead of working and sleeping in the mud, they created a relatively dry base for their operations.

When this site was first excavated, it was not immediately clear what the surface was, since today it is not flat, but tilted over 60° from the horizontal (Fig. 1). Today it is believed that this large cumulative tilt of the Pebble Man floor is the sum of

FIGURE 1 The 1.5 My-old tilted pebble platform of the “Pebble Men” at Ubeidiya, Northern Israel. (Photograph: Institute of Archaeology, Hebrew University, Jerusalem.)

small tilts by separate earthquakes on the nearby Dead Sea transform fault over the 1.5 My since the floor was created.

2.2 The Shanidar Cave

The earliest evidence we have for direct interaction between earthquakes and humans is from ca. 60 000 years ago in the Shanidar cave in the Zagros Mountains of north-eastern Iraq. Archaeologist Richard Solecki (1959) dug up four major ceiling collapses and some 20 minor ones. Several of these collapses (Fig. 2), which were almost certainly caused by earthquakes on a nearby seismically active fault, killed Neanderthals living in the cave. We know this because several of their skeletons, crushed by rock falls, were found beneath fallen blocks of stone.

2.3 Nineveh

The oldest written description of an earthquake is found on a tablet from the ancient city of Nineveh, (described by Ambraseys and Melville, 1982, following Thompson, 1937): “On 21 Elul, an earthquake took place. All the back part of the town is down . . . 30½ cubits therefrom being strewn and fallen on the near side of the town. All the temple is down . . . Let the Chief [architect] come and inspect.”

There is a curious story associated with this account. According to the code of Hammurabi, the ancient ruler of Nineveh, a builder was held legally responsible for the integrity of his building. In case of collapse, the punishment was his execution or that of his first-born son. This letter therefore is about the mitigating circumstances that would be

FIGURE 2 Sketch of the Shanidar cave showing the locations of Neanderthals crushed by earthquake induced roof collapses 45 000–70 000 y ago (after Solecki, 1959).

considered in this case, since earthquake-resistant design was probably not considered by Hammurabi.

2.4 Jerusalem circa 760 BC

This is the first clearly written description found in the Bible of an earthquake for which there is also independent archaeological evidence: “The words of Amos, during the reign of Uzziah, King of Judah, two years before the Earthquake.” (Amos 1:1). This earthquake devastated Jerusalem, and led to what might be viewed as a written description of strike-slip type fault motion, according to Zechariah (14; 4–5) “...And the mount of Olives shall cleave in the midst thereof toward the east and toward the west, and there shall be a very great valley; and half of the mountain shall remove toward the north, and half of it toward the south. And ye shall flee to the valley of the mountains; ... as ye fled from before the earthquake in the days of Uz-zi’ah king of Judah.”

3. Rise and Fall of Cities

3.1 Armageddon circa 1000 BC and 1200 BC

Not only did earthquakes periodically damage cities, they also created the landforms that made some of those cities politically and economically important. The Ancient city of Megiddo in Israel (Armageddon) shown in Figure 3 is a fascinating example of this (Davies, 1986; Nur and Ron, 1997a,b). Megiddo’s political and economic importance in the ancient world stemmed from its strategic position at the mouth of the Nahal Iron Pass through the Carmel-Gilboa Mountain range, an important route for ancient traffic between ancient Assyria and Egypt. However, the pass and mountain range which controlled

FIGURE 3 Location of Megiddo (Armageddon) (after Nelson, 1913).

traffic in the area at the time were the product of motion along the seismically active Mt. Carmel-Gilboa fault system (a branch of the Dead Sea Fault). The city’s proximity to the Mt. Carmel-Gilboa fault system placed it in an area of high earthquake risk. The great importance of Megiddo’s strategic location led to some of the greatest ancient battles fought in this region, and was the reason for the maintenance of its fortifications for close to 5 millennia (until ca. 500 BC).

Earthquakes were thus responsible for both the rise and the fall of Megiddo as an important walled city. Earthquake activity that shaped the land also explains the over 30 levels of excavated destruction of Megiddo, destruction sometimes assigned, for lack of a better explanation, to unproved battles. For example, King David’s often assumed (but not documented) conquest and mindless destruction of Megiddo may have actually been a destructive earthquake in Northern Israel around 1000 BCE (Kempinski, 1993).

4. Earthquake Indicators in Archaeological Sites

There is widespread disagreement about what constitutes archaeological evidence for earthquake destruction especially

FIGURE 4 A row of columns that fell during a strong earthquake in 749 AC, Susita, Northern Israel.

when acts of war, the more exciting explanation, can also be invoked. It is, therefore, helpful to consider some of the most telling features of earthquake damage found in archaeological ruins.

FIGURE 5 The Roman Colosseum: the missing half of the outside wall collapsed in an earthquake in 1349 (Guidoboni, 1994).

4.1 Fallen Columns

An attacker may, by the application of a great deal of manpower or ingenious leverage, topple the columns of a building. However, when an entire row of heavy columns (Fig. 4) is found toppled in the same direction, the sudden ground motion of an earthquake is the most likely explanation. A spectacular example is Susita, an abandoned ruin overlooking the sea of Galilee in Israel. It was a thriving place during Roman and Byzantine times, but began to decline in importance when the country was overtaken by the Arabs in 638 AD. However, the final blow was struck not by the Arab armies, but by the earthquake of 749 AD, which destroyed the temple that stood here, leaving behind the spectacular evidence of a row of a dozen parallel fallen columns, each weighing about 15 tons.

4.2 Collapsed Walls

The uniform toppling of walls is also a sign of earthquakes. When many similarly oriented walls at a site fell in the same direction, particularly when they bury grain, gold, or other valuables in their fall such as at Troy, Megiddo, Jericho, Mycenaean, and many other sites, the action of an army is an unlikely cause. An example is the Roman Colosseum where the

Kalat Namrood, Israel, 1202 AD

Coliseum, Rome, Italy, 1st Millenium AD

Long Beach, California, 1933

Stanford University, California, 1906

FIGURE 6 Comparison of slipped key stones at Kalat Namrood in Northern Israel by the 1202 AD earthquake with slipped key stones in the Roman Coliseum; a high school in Long Beach, California in 1933; Stanford University (1906).

entire southern part of the exterior oval-shaped wall is today missing (Fig. 5). It collapsed during an earthquake in 1349 AD.

4.3 Slipped Keystones

In buildings built with unreinforced arches, earthquakes sometimes cause one or more of the wedge-shaped stones to drop down until the arch is again wedged tight. If the slip is large enough, the entire arch collapses; if not, the dropped keystone remains as clear evidence of the disruption. Four examples, two older ones (Nimrod in Israel ca. 1200 AD, and the Colosseum in Rome, Italy 1349 AD (Guidoboni, 1994)) and two modern ones (Geology corner at Stanford University 1906 and the Long Beach high school entrance, California 1933) are shown in Figure 6. In all four cases, as indicated by the arrows in Figure 6, the bases of the arches slipped sideways due to motion in the earthquake, loosening the key stones in the arches.

5. Crushed Skeletons

People do not intentionally bury their dead in the rubble of collapsed buildings. Likewise, when a building is under attack and soldiers are laboring to topple a wall, few would wait long enough to be crushed beneath the stones. Thus the presence of crushed skeletons beneath ruined buildings is accepted by most archaeologists as some of the best evidence of collapse due to an earthquake. One example, already mentioned, is the Shanidar Cave in Iraq (Solecki, 1959) in which eight Neanderthal skeletons were uncovered. Apparently, some of these people were killed by earthquake-induced rock falls from the cave ceiling. One skull was found crushed on top of a stone, with a pile of rocks on top of it. The nature of the breakage indicates that the victim was probably alive and standing upright when the falling rock mass struck him.

One of the strangest stories of crushed skeletons was uncovered in Arkhanes on the island of Crete, Greece. Yannis Sakellarakis and Efi Sapouna-Sakellarakis (1981) discovered here the ruins of a Minoan temple that had been destroyed around 1700 BC by a large earthquake that also destroyed many other palaces on Crete. In one of the rooms of the temple the skeletons of a priest and his female acolyte were found on the floor before a typical Minoan altar. The priest had his arms thrown up to protect his face. On the altar was the skeleton of a young man reclining on his right side, and probably bound hand and foot. Lying on his bones was a ceremonial knife; indeed, it appears that a destructive earthquake had interrupted a religious rite of human sacrifice in full swing!

A heartbreaking example of earthquake casualties was uncovered by David Soren (1985) and his colleagues in the ancient Kourion, Cyprus. The earthquake destroyed the town at dawn on 21 July 365 AD, when most of the city was still asleep. The excavations revealed entire homes and stables that

FIGURE 7 A family – man, woman and 1-year-old baby – crushed under their home that collapsed by the 370 AD earthquake in Kourion, Cyprus (Soren, 1985).

had collapsed, crushing people and animals inside beneath the rubble. So many skeletons were found, and the site was so undisturbed after the earthquake, that Soren said he and his colleagues “felt like a rescue team arriving 16 centuries too late.” The most moving find here was the discovery of a family – a man, a woman, and their one-year-old child – killed under their collapsed home (Fig. 7). It appears that the three had little time to awake and realize what was happening, for their skeletons seem caught in a pose of sleep.

6. Regional Earthquake Damage

The effects of earthquakes are not limited to one site but may cause damage to structures over an area on the order of thousands of square kilometers. Although some of the effects of earthquake destruction have been recognized in archaeological excavations for decades, few archaeologists have applied their theories of earthquake destruction outside the boundaries of their own excavations onto a regional scale. However, historic records and archaeological evidence clearly demonstrates the

regional extent of damage caused by many past large and even moderate earthquakes. A few examples are described here.

6.1 Holy Land Earthquake in 363 AD

By combining written evidence and dated excavated ruins throughout the region, one can construct a map showing the

FIGURE 8 The extent of severe damage caused by the strong 363 Holy Land earthquake. The damage zone is 440 km long suggesting a possible magnitude of 7.7–8.0 (after Guidoboni, 1994).

sites affected by this historically well-documented earthquake (Fig. 8, Guidoboni, 1994). Russell (1980) has suggested that severe damage occurred as far south as the Nabatean city Petra. Recent excavations have revealed the destroyed remains of the oldest church in the world in Aqaba, Jordan—some 120 km further south of Petra (Parker, 1998). The northernmost damaged site is Dan in Israel, 440 km from Aqaba, suggesting a possible magnitude of 7.5–8 for this earthquake.

6.2 The North Anatolian Fault System

Two particularly destructive earthquakes of this active fault system in the Eastern Mediterranean are considered here.

The first occurred on 17 August 1668, with a probable magnitude of 7.5–8.2. To the intensity VII region, mapped by Ambraseys and Finkel (1988) from written reports, we have added the location of Hattusas, the ancient capital of the Hittite empire (Fig. 9). Hattusas was of course just a ruin in 1668. However, it was a thriving great power when it was destroyed inexplicably at the end of the Bronze Age ca. 1200 BC (Yon, 1992). This superposition illustrates the possibility that in 1200 BC Hattusas may have experienced an earthquake perhaps like the 1668 event; if so, the city could not have escaped major damage, perhaps even total destruction, and subsequent abandonment (Nur and Cline, 2000).

The second large earthquake struck in Western Turkey on 9 August 1912. To the map of damage caused by this

FIGURE 9 Location of Bronze Age Hattusas, the Hittites capitol, well within the intensity VII contour for the August 1668 earthquake on the north Anatolian fault in Turkey (after Ambraseys and Finkel, 1988).

FIGURE 10 Location of Bronze Age Troy, well within the intensity VIII contour of the 9 August 1912 earthquake in north-western Turkey (after Ambraseys and Finkel, 1987).

earthquake, published by Ambraseys and Finkel (1987), we added the location of ancient Troy (Fig. 10) which falls inside the intensity VIII contour. Of course, Troy was only an archaeological ruin in 1912, but if this kind of earthquake ever struck while Troy was a thriving city it would have resulted in great damage, and possibly even total destruction. Archeological evidence does in fact suggest that Troy VI or VII was badly damaged by an earthquake of similar intensity (Blegen *et al.*, 1953, 1958).

As can be seen from these few examples, damage from large earthquakes is regional in extent. It is therefore important to consider the effects of earthquakes in the archaeological record on a regional scale, to attempt correlation between sites, and even to consider the effect of such widespread damage on a civilization's economy and infrastructure.

7. Earthquake "Storms"

One of the most important aspects of the occurrence of large earthquakes in the Eastern Mediterranean and Near East is their apparent tendency to occur in episodic bursts of activity or "storms." The modern history of large earth-

quakes along the North Anatolian fault illustrates this phenomenon. A series of earthquakes, from 1939 through 1999, together released tectonic strain by unzipping this entire plate boundary over approximately 70 y (Stein *et al.*, 1997). The strain released by the surface slipping of this earthquake sequence (about 4 m on average) must have taken a few hundred years to accumulate. Consequently we should expect such storms to recur only every few hundred years with relatively quiet periods in the interim.

A great "earthquake storm," consisting of a dozen or so earthquakes, appears to have unzipped not just one but several plate boundaries throughout the Eastern Mediterranean over a vast area in the 4th century AD, between 350 and 380 AD (Fig. 11). This 30 y period appears to have been preceded and followed by relatively quiet periods, probably for about 300 y.

It appears therefore that, in general, large earthquakes in the Eastern Mediterranean tend to occur in episodic "storms" that unzip the main plate boundaries during short, 30–100 year, periods separated by 300–500 years of relative quiescence. The implication of this for archaeology is that a great deal of physical damage over a large area and the resulting societal effects are expected to have happened during relatively short periods of time.

FIGURE 11 The location of sites damaged in the 4th century AD earthquake “storm” in the Eastern Mediterranean (after Guidoboni, 1994).

8. Earthquake Storms, System Collapse, and Human Conflicts

The prevailing opinion among many archaeologists and historians has been that earthquake destruction has not been sufficient to substantially affect the social order. It is true that a healthy city or nation with a robust economy can rebuild relatively quickly after even a major earthquake, possibly achieving complete recovery within a few decades. However, in areas and periods of social tension, unrest, or economic decline, an earthquake can indeed be the trigger for social overturn.

One instance is the Holy Land earthquake of 31 BC. Because of its intensity in Jerusalem, the earthquake caused portions of the city’s walls to collapse (Josephus Flavius). Occurring during a state of war between the Arab nation in today’s Jordan and the Jewish nation in Jerusalem, this prompted an Arab attack on Jewish-held Jerusalem. In this case, the city held, but had the earthquake damage to the city walls been slightly greater, the outcome could certainly have been different.

In another example, the slave uprising at Sparta in about 469 BC may have been triggered by a large earthquake, which greatly damaged the defenses of the city that sheltered the ruling elite. “...The Spartans began to practice these

cruelties...after the great earthquake when the Helots and Messenians together attacked Spartans, causing widespread damage...and putting their city in great danger” (Plutarch, “The Life of Lycurgus”).

The grandest historical event (although without written evidence) that may be related to earthquake storms is the catastrophic ending of the Bronze Age (Schaeffer, 1948; Nur, 1998; Nur and Cline, 2000). This system collapse over the entire Eastern Mediterranean region has been well known to historians and archaeologists for over a century, yet the cause remains an enigma to this day.

Figure 12 captures the magnitude of this catastrophe by showing some of the main sites that were physically damaged or destroyed in the Eastern Mediterranean at end of the Bronze Age ca. 1200 BC. Evidently, the collapse of cities and nations occurred over a period of some fifty years between ca. 1225 and 1175 BC.

The prominent French archaeologist Claude Schaeffer proposed in 1948, well before the emergence of the theory of plate tectonics, that one or several earthquakes were responsible for the end of the Bronze Age (Schaeffer, 1948). Schaeffer’s idea was widely rejected and even spawned an anti-earthquake bias among archaeologists that persists to this day. For example Elizabeth French wrote in 1996: “Archaeologists of my generation, who attended university in the

FIGURE 12 The Aegean and Eastern Mediterranean sites destroyed ca. 1225–1175 BC (after Drews, 1993) superimposed on the Aegean and the Eastern Mediterranean regions in which the intensity was greater than VII (after Karnik, 1968).

immediate aftermath of Schaeffer's great work in 1948, were brought up to view earthquakes, like religion, as an explanation of archaeological phenomena to be avoided if at all possible. Thus, it is only recently that an earthquake at Mycenae has begun to be a serious hypothesis."

Figure 12 shows also the contours for Mercalli intensity VII ground motion for large earthquakes in the area (after Karnik, 1968). The result is very suggestive; most of the destroyed sites fall within the high intensity regions, so they have most likely been badly damaged by earthquake at some time in their past.

Although there are no written records going back as far as 1200 BC, there are over a dozen skeletons found crushed beneath collapsed buildings at sites that were destroyed at the end of the Bronze Age (Nur, 1998; Nur and Cline, 2000). As described earlier, this sort of evidence is suggestive of the impact of earthquakes.

As pointed out by Nur (1998) and Nur and Cline (2000), it appears that earthquakes, most likely through an earthquake storm, could have been responsible for ushering in the physical collapse at the end of the Bronze Age. Of course earthquakes alone probably have not destroyed entire societies or powers. More likely they rendered cities and population centers vulnerable, even defenseless to human attack and at times even invited attack, such as in Jerusalem in 31 BC, Sparta in 469 BC, and perhaps in Jericho ca. 1400 BC. In other words, at the end of the Bronze Age, an earthquake storm

could have triggered or enabled wars and attacks which then struck the finishing blow to civilization throughout the Eastern Mediterranean.

9. Conclusion and New Questions

There are several reasons why the study of earthquakes in archaeology could be important and should be better incorporated into the interpretation of archaeological sites. First, it provides a much better understanding of the impact of natural disasters on history, when there is no consensus on this (see Tainter, 1988). For example, Ambraseys (1971) adamantly states, "Earthquakes in the past twenty-five centuries have had little, if any, serious influence on historical developments in the Middle and Near East...but they have never caused the ruin of a culturally advanced state, far less the end of a civilization..." Under usual circumstances, Ambraseys is correct. Earthquakes are instantaneous events that cause sudden damage, but societies generally can recover even from the severe damage a large earthquake causes. However, when the effects of a series of earthquakes is compounded with wars or economic difficulties, the end result can be cataclysmic.

While Ambrasey questions the impact of earthquakes on societies, Rapp (1986) questions the evidence itself: "Without direct evidence for seismic destruction, earthquakes should be 'explanations of last resort' in archaeology." However, if an area is known to be susceptible to earthquakes (from geological and geophysical evidence), then earthquake damage is as respectable a hypothesis for destruction, unless historical or archaeological evidence suggests otherwise.

An important geophysical question that may be contributed to by archaeological evidence is how, when, and where historical and prehistoric earthquakes occurred. If earthquake storms are indeed a central feature of the time/space distribution of large earthquakes—their clustering in time is the process that unzips plate boundaries—then our thinking about how earthquakes accommodate plate motions may require important revisions. The storm process implies, for example, that large earthquakes on one fault or fault segment interact with faults many rupture lengths away, much farther than the current theories of plate deformation suggest. For example, can a 70 km long earthquake rupture associated with a magnitude 7 earthquake near Jericho somehow lead to a magnitude 7 earthquake in say Sicily or Western Greece?

The earthquake storm pattern also has an obvious consequence for earthquake prediction research; the probability of a large earthquake during the long "quiet" period may be an order of magnitude lower than during the active "storm" period. This may be applicable, for all we know, not only in the Mediterranean region but also in other areas of complex plate boundaries, e.g., China, Central America, even California, where sufficiently long historic and prehistoric

records are not available and therefore we cannot even tell whether activity is governed by storms at all.

The conjunction of earthquake science and archaeology is a field that is ripe for study. Although most of the data to date are anecdotal in nature, improvements in both archaeological methods and geophysical understanding should allow a much better understanding of how earthquakes affected ancient civilizations. Furthermore, both sciences would benefit from collaborative work. Earthquake prediction efforts may be helped by extending the earthquake record back into prehistory, and archaeologists may gain a new understanding as to the types of damage earthquakes or earthquake sequences could have caused at their respective sites.

Historical Seismology: the Long Memory of the Inhabited World

Emanuela Guidoboni

SGA, Storia Geofisica Ambiente, Bologna, Italy

1. What is Historical Seismology?

For a number of years, many seismological, geophysical, and seismological engineering conferences, especially in Europe, have devoted a section specifically to this field of study. It is in fact now accepted that historical data provide valuable information about the “size” and frequency of past earthquakes, and this contributes to the formulation of seismic hazard and risk estimates and the location of active faults, especially where particular geological complications make their identification difficult. Historical seismology (not to be confused, of course, with the history of seismology) is that branch of seismology which uses historical data to identify the effects of past earthquakes and to answer specific seismological questions: when, where, and how large did these earthquakes occur? Nobody teaches this discipline, and (so far, at least) it has no positions in academic institutions or schools; and yet it produces data which require financial investment and continuity of effort. As a discipline, historical seismology can be considered to stand at the point where historical research, from which it takes its research methods and interpretative rules, “intersects” with seismology, from which it takes its problems and aims. It is thus at one and the same time a type of seismology, in that its results relate to that discipline, and a type of history, since its data derive from specifically designed historical research.

The aim of historical seismology, therefore, is to gain an understanding of those past earthquakes, which no longer have a place in human memory. It is true that there were some who studied historical earthquakes even before the days of modern parametric catalogs, but they did so in a quite different way. The change in methodology came with the diffusion of computers, which began to spread into the principal research centers in the 1970s, and proved to be particularly suitable for dealing with all kinds of basic data, including those concerned with earthquakes. The introduction of computerized catalogs brought with it a revolution in the way information about

historical earthquakes was dealt with, because it necessitated the conversion even of their less objective aspects into parameters and codes which could be handled in automatic form. Solving this important conceptual problem led to the introduction of far more modern techniques for the analysis of historical seismicity, affecting both the speed with which all the information concerning an area or site of interest could be extracted, and the possibility of dealing with this information not only in a qualitative way, but also using statistical methods.

Data from historical sources have been summarized only in part in traditional parametric earthquake catalogs. The fact is that extremely important assessment factors, which we now try not to lose sight of, are excluded from traditional earthquake lists. The most advanced catalogs are nowadays effectively information systems in which data are presented in a critical way, and grouped according to research levels or within a preestablished logical hierarchy. Among the countless available items of information, some are obviously suitable for calculating traditional parameters; but there are others suitable for “recalculating” them along new and more sophisticated lines, without it being necessary to go back to the basic descriptive data.

Although historical earthquake catalogs vary in quality from one country to another, they nevertheless have in common the fact that they are all based on descriptive data derived from human observation, that is to say, from the long memory of the inhabited world. Nevertheless, those who use these catalogs (whether seismologists, statisticians, engineers, or geologists), usually do not know or have only a hazy idea of the research processes, methods, and problems underlying the data which are available to them. Consequently, they often do not know how these data could be improved, verified, or used to better purpose; and this happens because historical seismology is in essence a multidisciplinary field. It seems quite strange to observe that underlying the relationship between those who produce these data (historians) and those who use them

FIGURE 1 Timescale and disciplines which “capture” earthquakes.

(seismologists) there has developed a practice based almost on a “nonformalized epistemology,” which to some extent recalls the old antithesis between word and number, or subjective and objective – a sort of “fossil guide” to European positivist culture. Although numerous theories about the complexity of knowledge have on the one hand taken away a certain amount of optimism and self-confidence, they have also, fortunately, made clear the limits of “languages” in the broadest sense of the term (words and numbers, that is to say), and the unending possibility of arriving at new interpretations. These profound changes in our cognitive context are today capable both of encouraging the various disciplines involved in the study of earthquakes to listen to one another more attentively, and of opening up new perspectives (Fig. 1).

2. The Cultural Roots of a Science of Earthquake Observation

The mid-20th century decisions taken at Strasbourg and Utrecht set in motion, perhaps without foreseeing the consequences, an exceptionally influential historical data reassessment process. In many countries in the Far and Near East and the Mediterranean area, there already existed a very ancient tradition of studies and works on earthquake effects and the interpretation of their origin, which provided a sort of “seed bed” for this kind of research.

In the Mediterranean area, for example, earthquake geography already existed as early as Greek and Roman times, and there was a conviction that some areas were more seismic than others. There were numerous naturalists and literary texts describing ancient and contemporary seismic phenomena and their interaction with the inhabited world, thereby demonstrating that there was an interest in the “historical” even in ancient authors writing about earthquakes. But apart from such deliberate use of historical information by writers of the past, there is obviously also “involuntary” written evidence of seismic effects. Data of this kind have managed to survive even from very ancient times, and they are material for historical seismology. The earliest written evidence of an earthquake is the so-called “Letter from Niniveh” (Assyrian Empire), dating to the 13th century BC. It records the restoration of the temple of Emasmas and the tower gate in Niniveh, both of which had been damaged by a violent tremor (Thompson, 1937).

China has an important and very ancient tradition of references to earthquakes, the earliest of which goes back to 1177 BC (Academia Sinica, 1970). Earthquakes, like celestial phenomena, were signs to be interpreted for court horoscopes, and hence their occurrence was recorded in the registers of the astronomical office of the Chinese court. Perhaps for this reason, however, and in spite of their undoubted historical and cultural value (Needham, 1959), the ancient data which have survived are rather slight in quantity and quality and are now difficult to use (Lee *et al.*, 1976; Lee and Brillinger, 1979). But the more recent data, especially from the Ming dynasty (about mid-14th century) onward are useful.

As far as the Mediterranean area is concerned, the earliest information about real earthquakes (that is to say, those for which a location and time are provided, as opposed to those which are in some way myth-related) goes back to about 760–750 BC. It concerns an earthquake, which struck Jerusalem and the valley of Hinnom. Of the rare earthquakes mentioned in the Bible, this is one for which there is other evidence in Hebrew and Greek sources (Guidoboni *et al.*, 1994). In other cases, it is religious symbolism, which predominates. The first earthquake in Persia to be recorded in history, on the other hand, is one, which destroyed the region of Ray in the 4th century BC (Ambraseys and Melville, 1982).

But apart from the rarity and curiosity value of the earliest data, which are often difficult to put to practical use, present-day historical seismology needs to be able to establish detailed seismic effect scenarios, in order to add to the quality and quantity of entries in historical earthquake catalogs. The aim is to bring the image of apparent seismicity (that is to say that part of seismicity which it has been possible to reconstruct by means of historical seismology) as close as possible to actual seismicity. From this point of view, research acquires a special scientific significance when there are substantial quantities of evidence available from sources which were produced on a regular basis and have been well preserved (archive documents and manuscripts). An analysis of the effects of a past earthquake involves various fields of investigation, from the history of administration and institutions (responsible for dealing with the disasters) to that of material culture (the means and techniques of building construction) and that of the history of ideas and culture (the reception and interpretation of the earthquake). It is not always the case that a country’s history permits such a systematic and broad approach; but even a few written remains can be illuminating.

The preservation of this particular kind of historical record in modern Europe has a tradition, which began in the Italian Renaissance in imitation of classical texts. Thus, the first known catalog of historical earthquakes was written in 1457 by Giannozzo Manetti (1396–1459). It is preserved in various manuscript codices, and records 70 seismic events from antiquity to the 15th century, together with sources. From the 16th century onwards, an erudite fashion for compiling lists of past earthquakes became widespread, as part of a renewed interest

[illegible]

FIGURE 2 Title page of the manuscript treatise (Archivio di Stato di Torino *Trattato di diversi Terremoti*, 1570–1574) by Pirro Ligorio, famous architect of the late Italian Renaissance. This precious catalog contains also a project for a seismic-resistant house (Guidoboni, 1997).

in “signs” and all those phenomena which were generally considered to be “prodigious.” This resulted in the production of a number of earthquake lists, though they were obviously not intended for practical use. Among the most important were those of Conradus Lycosthenes 1557 and Pirro Ligorio (manuscript) in 1574 (Fig. 2).

In the more advanced court circles in Italy in the second half of the 16th century, a sort of “theoretical anxiety” was expressed in relation to earthquakes. This undermined previous faith in the Aristotelian theory, and brought into being a new attitude which, in spite of its fragile and contradictory nature, led to the production of extensive and detailed descriptions of seismic sequences. Descriptions of phenomena which were not understood were deliberately passed on “to

posterity” in the hope (as is explicitly stated in a manuscript of 1570, Ferrara, Biblioteca Comunale Ariostea, J. de Robertis, cl.I, 294) that someone would find a use for them in the future. There were various earthquake theorists and compilers in the 17th century, but it was above all Bonito’s catalog (1691) which became a sort of “ideal” archetype for earthquake catalogs of modern Europe. It is a unique product of literary and historical erudition, with boundless geographical interests (even listing earthquakes in Japan and Latin America) (Fig. 3).

In the early 18th century, central Italy was struck by a very long and violent seismic sequence, consisting of three strong earthquakes. They lasted from January to February 1703, even causing damage in Rome. The first earthquake “diaries” date

FIGURE 3 Bonito’s Catalogue (1691): contribution of different typology of historical sources and various traditions. This is an example of the cultural contexts from which we derive the historical European earthquake catalogs (from Guidoboni and Stucchi, 1993).

from this time. Subsequently, and particularly after the earthquake which destroyed Lisbon in 1755, the attention of physicists and naturalists was particularly drawn to the study and theoretical interpretation of striking seismic events in their individuality, so that the compilation of earthquake catalogs became a matter of secondary concern (Seyfert, 1756; Bertrand, 1757; Moreira de Mendoca, 1758).

This process of observation reached its most intense toward the end of the 18th century (Fig. 4) when the five great earthquakes, which devastated Calabria from February to March 1783, aroused a sort of descriptive frenzy amongst scientists and naturalists. Thousands of pages were written simply to describe that interminable seismic sequence (it lasted for several years) and all its effects. They wanted not so much to interpret, as had previously been the case, but to observe. That extraordinary effort left its mark on European culture and consciousness.

What happened in this field is certainly better known for the 19th century than for earlier periods (see Valone, 1998). To mention only the most famous names, they were David Milne (1805–1890), Robert Mallet (1810–1882), and Karl Ernst Adolf von Hoff (1771–1837). Giuseppe Mercalli (1850–1914), and finally Mario Baratta (1868–1935), who laid the foundations for the first systematic organization of historical earthquake data. Although all these men were primarily specialists, they were also scientists with many scholarly interests, and so they promoted “learning.” But multidisciplinary science was still beyond the horizon.

Some aspects of historical seismology research are of principal interest in the seismological and geophysical spheres, but it can also reveal how historical building techniques have been modified with the passage of time in order to mitigate the effects of successive earthquakes.

3. Sources for Historical Seismology

3.1 Types of Sources

Even in the most different historical contexts, geographically and culturally far apart, historical seismology finds its basic data in the same three great record “containers”: (1) individuals (chronicles, letters, diaries etc.); (2) institutions (archive sources); and (3) scientific field.

Countries with an ancient written culture and intense seismic activity have almost all developed and consolidated their knowledge of past earthquakes over the centuries, often producing treatises or earthquake catalogs of considerable cultural importance; but they are not always immediately usable today. The old antiquarian and positivist tradition used sources – if it used them at all – only after extracting them from their cultural and territorial context, as though they were fragments of lost records which had been deposited, sometimes by chance, in the tradition of literary or historiographical texts. In the closing decades of the 20th century, however, an effort has been made to go back to the original sources as reliable evidence, to render them usable by means of a process of analysis and treatment, and in doing so to make thoroughly clear the process of evaluation and use of the data involved (Fig. 5).

3.2 Sources Deriving from the Memory and Observations of Individuals

In old and traditional earthquake catalogs, a quite privileged position was occupied by chronicle sources, i.e., sources deriving from the memory of individuals, and from their desire to narrate and describe. The presence of these data sources in

FIGURE 4 This graphic synthesizes available information on the proceeding of the shocks during the earthquake from 4 April to 12 December 1781, which destroyed an area of the Romagna Apennines (Northern Italy). An example of the shocks attested by direct and independent witnesses.

FIGURE 5 Italy represents a particular case for the availability of sources in a temporal frame of 2500 years. The graphic shows the prevailing typologies of sources and their availability in time from the 5th century BC up to the 20th century AD. Since the end of the 16th century various typologies of independent sources guarantee a good level of nationwide, informative coverage. Nevertheless this does not imply the “completeness” of the catalog, which still needs work to be pursued.

old catalogs now necessitates a painstaking analysis of the texts concerned, how they are related and what they derive from, in order to throw light on the possible transmission of errors into the first earthquake lists and from there into earthquake catalogs. Hasty or inexperienced critics have often tended to denigrate chronicle sources, thereby mistaking the effect for the cause, so to speak; their own poor or inadequate work being interpreted as a limitation in this kind of source itself, so that the texts concerned were judged to be unimportant or unreliable.

It is certainly true that making use of personal memories requires dedication as well as profound knowledge and a particular critical sensitivity. For such sources are personal universes, immersed in their own time and permeated with their own culture; and so they are very powerful “filters” placed between the actual phenomena and our present hope of understanding them. Only by strictly appropriate means and scrupulous care can we derive from these sources an understanding of many aspects of earthquakes, which would not otherwise be available to us. In the first place, we have to compare the various independent reports of a single event, paying particular attention to those aspects of the individuals’ reports which are or are not in agreement with one another, for example, local effects, effects on buildings, and even the perception of the duration of the tremors in a seismic sequence. Secondly, an analysis of these reports makes it possible to correlate data from the individual record with those from public institutions, and hence to pick out complementary information, confirmations, and additions, as though one were dealing with a difficult jigsaw puzzle. This is not a literary exercise, therefore, but rather of a method of work designed to utilize traces of human memory as though man was a very special “seismograph.” And the results can justify the effort, because human memory and perceptiveness have in various ages and in quite different parts of the world made a quite extraordinary contribution to our understanding of seismic events, by describing their effects on the environment and on the buildings of the time.

This “network” of data about inhabited areas has today allowed us to learn about large seismic sequences of the past, nondestructive effects in places far from epicentral areas, low-energy local earthquakes, or deep, high energy tremors with very extensive felt areas (Fig. 6).

3.3 Sources Produced by Institutional and Administrative Bodies

Although personal sources are very valuable, historical seismology’s most important contribution in recent years has come from research in the field of institutional and administrative sources. Unlike sources based on the individual memory (where there is an intention to leave traces), institutional sources are produced within the framework of administrative, bureaucratic and legal rules and customs, as applying to the government of a particular territory. Precisely because of their “involuntary”

nature, these involve fewer subjective influences affecting our attempt to understand the key factors in the effect of a seismic disaster (or at least its damage effects) on the buildings and economic and administrative structures of a society: what can be defined as seismic impact.

Institutional sources are preserved, of course, in archives. These are complex historical memory structures, which partly reflect the structure of organizations, offices, and official committees – in broad terms, that is to say, of the administrative, political, and jurisdictional authorities, which produced them.

Archive sources of interest in the assessment of seismic effects are those concerned with the administrative and financial decisions taken after a destructive earthquake in order to deal with the emergency, control and plan reconstruction, and organize a return to normal habitational conditions. It often happens that the cultural or political importance of the places affected has resulted in earthquakes being mentioned in diplomatic correspondence, as can be seen in the vast number of such diplomatic exchanges preserved in European archives. But of even greater importance for our understanding of the impact of a destructive earthquake within its economic context, are the communications between the various administrative hierarchies, and between central and peripheral authorities, whether political, administrative, or religious. Because we need to understand and make use of documentation of this kind, it is also important to understand the very many extratextual factors concerning both how individual institutions work (a matter of administrative, and political history), and the relationship between institutions and earthquake-affected localities, within the network of relationships which operate after a strong earthquake between central and peripheral authorities, and between authorities and others (whether public, ecclesiastic, or private) who are at the place concerned.

As far as this specific research field is concerned, there are two special stages involved in sound archive work: (1) the translation of seismological questions into historiographical questions; and (2) the translation of historiographical questions into archive searches. Where archives are concerned, one has to be guided by the need not just to find material or subject matter directly connected with earthquakes, but also to identify in an organic way the documentation produced by institutions in relation to their role in the postearthquake phase, i.e., documentation which will be closely connected to administrative, financial, and juridical control over the places affected.

3.4 Sources Produced by the Scientific Institutions of the Past

The third type of source consists of the evidence produced by scientific bodies of the past, which were concerned with earthquakes. In some countries, such as Italy, they came

FIGURE 6 Map of effects of the 1222 earthquake in northern Italy. Historical seismology allows us to acquire information on the effects of earthquakes, even the ones from the remote past, and often with a surprising amount of detail. In this case, among the numerous examples now available, the map portrays the effects of the earthquake occurring on 25 December 1222 which hit northern Italy ($I_0 = \text{VIII}$ MCS scale; M_e 6.2). This earthquake had for a long time been turned into a legendary event, as a catastrophe of “European” proportions, by historiography and the early seismic catalogs. By the mid-20th century it had entered the parametric Italian catalogs being classified as one of the strongest earthquakes in this area ($I_0 = \text{XI}$ MCS, M_e 6.8). But the critical analysis of the accounts of the monks, the notaries and above all of the Pope’s chancellery have brought to light less destructive effects, more compatible seismotectonic characteristics of the affected area (from *Catalogue of Strong Italian Earthquakes*: Boschi *et al.*, 2000). The pattern highlights the most affected area, as indicated by the medieval contemporary sources (the area south of the Brescia dioceses).

into being in the mid-18th century through the activities of academies. In the 19th century, centers were set up and organized specifically for this purpose, in the form of observatories or geodynamic and meteorological services run by private individuals who often belonged to religious orders (e.g., Barnabites and Pietists). These bodies produced bulletins, macroseismic postcards (rudimentary but effective questionnaires about local earthquake effects), field surveys, and damage reports, which governments were already beginning to demand. There has so far been no worldwide systematic collection of these texts (there is in fact no data bank where they can be accessed), but together with the first instrumental data, which are material for the history of seismology (Ferrari, 1992, 1997), they constitute a data heritage

of great informational value which has not yet been fully utilized.

All these materials, with their different aims and authorship, contain important information about earthquake effects as they occurred, and they now add in a very special and specific way to the information in documents and historical sources of an archival or personal kind belonging to the same period. These sources have been taken into consideration during the infancy of modern seismology, but have often been misunderstood and neglected, even within the seismological sphere (as qualitative data, they have been considered out of date and irrelevant); and to gather them together and utilize them in a systematic way today requires a substantial effort of organization.

4. Earthquake Effects on the Environment

Historical descriptions of the effects of strong earthquakes on the environment are important, but often scattered or neglected. Information of this kind can be found not only in reports belonging to recent centuries but also in ancient texts; and they provide valuable material for seismotectonics and the location of active faults. It is not easy to classify this material, because one has to understand the cognitive framework and means of expression used in producing such descriptions. At times they may appear to be figments of fantasy, but they can be used if decoded and contextualized. Perhaps partly for this reason it is matter of interest that the third and latest edition of the new “Catalogue of Strong Italian Earthquakes” (CSIE) (Boschi *et al.*, 2000) contains more than 2000 codified and georeferenced environmental effects.

Now, although the memory of what happened a few decades ago is already fading, we have access to information about data of this kind as preserved in ancient texts. For in the ancient and late Roman world, the effects of earthquakes on the environment made a great impression on the minds of observers, due to that sense of the sacred and magical with which natural phenomena were imbued, and new attitudes that sometimes led to the idea of “nature” as unchangeable and mysterious. Indeed, seismic effects are often recorded in the sources with such emphasis that the direct cause fades into the background, so that today’s reader may sometimes doubt whether the phenomenon described really was caused by an earthquake. In the Roman world, moreover, earthquake effects were seldom even mentioned, especially if they related to smaller settlements.

Evidence about the early Middle Ages was mainly produced in a monastic environment and therefore in very important, though not urban, cultural contexts. One might think that this would lead to a greater number of direct observations of effects on the environment being made. However, the culture that permeated the production of such observations did not favor explicit and direct observation of these phenomena. Take, for example, the description of the effects of the earthquake of 3 January 1117 on the waters of the Po in the heart of the river valley (see the attached Handbook CD, CSIE, in Boschi *et al.*, 2000). A written narrative tells us that the waters came to a standstill and rose up “like a bridge,” this being interpreted as a sign from God; but since we now know how such phenomena occur, we may have good reason to examine this information from a different viewpoint.

Language often envelops such phenomena in an aura of legend, telling of mountains that split in two, smoking and roaring. How to reinterpret this type of strongly figurative language within our present cognitive models is not immedi-

ately obvious. In general, however, a better understanding of the meaning of often fantastical descriptions only becomes possible when certain effects are repeated in the same areas in later periods. Thus, if the splitting of a mountain can be explained with reference to fractures in the ground and the smoke to dust raised by the rolling of boulders, perhaps the roaring can be identified as the acoustic perception of low frequencies, possibly amplified by particular conformations of the subsoil.

Ever since the beginning of modern times (i.e., since the 17th century), descriptions of environmental effects have become the subject of discussions about the real origin of seismic phenomena; natural philosophers, physicists, and naturalists began to observe the splitting of the Earth, phenomena of liquefaction of the ground (leading to general or differential subsidence of foundations), the emission of flaming gases, poisonous exhalations and even phenomena of ionization of the air [“red sky,” see Ferrara, Italy 1570 in *Catalogo dei Forti Terremoti in Italia* (Boschi *et al.*, 2000)].

The great observational leap toward descriptions which were more accurate and more immediately valuable within current scientific frameworks took place in the 18th century, clearly as the result of huge progress in the sciences and naturalistic thought. Descriptions of the effects of major earthquakes had already in the previous century proved to be aware of the marks left on the environment. An example may be seen in descriptions of the environmental effects of the earthquakes in Calabria (Southern Italy) in 1638, which were also responsible for creating a fairly large area of marshland near Sant’Eufemia (about 180 km²) and a fracture about 11 km, 50 cm wide and 75 cm difference in level of one side compared with the other on the eastern slopes of the Sila mountain. The earthquake at Sannio (Southern Italy) in 1688 is another case in point. Despite the use of fairly general terms like “splitting” and “fissures” in the descriptions, the authors may perhaps be referring to much more complex phenomena, thus providing potentially important information about the seismic source.

4.1 Parameters

Moving from words to numbers is not easy, as can be seen from the whole complex question of parameters in historical earthquake catalogs (a matter, which perhaps deserves more discussion than it has received).

In the scientific world of seismology, macroseismic data are commonly considered to be information of a qualitative kind and therefore somewhat unreliable and generally inferior to instrumental data. This leads many workers in this sphere to reject such information, considering it to be nonscientific. Criteria for the estimation of epicentral and energy parameters for historical earthquakes have in fact rarely been given precise official standing in the past, and qualitative assessment techniques have often been adopted,

partly because in many cases the information was not available in a form which lent itself to analytical treatment. Special techniques and algorithms are now used for defining time of origin, epicentral coordinates, epicentral intensity, and equivalent magnitude, as recorded in brief database records. What is probably most important in this process, apart from a clear description of the criteria for assessing the reliability of these estimates, is that decision processes themselves should be open to checking. But let us now consider one by one the principal parameters concerned: date, intensity, epicenter location, and estimated magnitude.

4.2 The Measurement of Time

The time of origin of an earthquake as given in catalogs is often treated as though it was beyond doubt, so that it acquires the status of an identification label. This would be valid in principle if the date and time of an earthquake had indeed been accurately established. In practice, however, this is not the case, since catalogs often do not take into account the date and time conversions necessary to align all historical earthquakes within the same time reference system, conventionally agreed as Greenwich Mean Time (GMT) in earthquake catalogs. In Italy, for example, a series of different dating styles and timescales have been used at different periods and in different places. For this reason, the conversion of historical dates and times to GMT requires careful attention and specific conversion methods, which were unknown to some compilers of previous catalogs. In the most serious cases, this lack of knowledge has led to the duplication even of high-intensity earthquakes. The problem has been approached by few authors (Dominici and Marcelli, 1979; Ferrari and Marmo, 1985), and a solution has not yet been fully absorbed into scientific practice.

Attempts to establish the exact date of occurrence of historical earthquakes from descriptions in the sources have highlighted two types of problem: (1) the difficulty of identifying a universally agreed date; and (2) that of converting it into current dating practice (Fig. 7). Countless pages have been written about the dating problems resulting from ancient calendars, for they have led to mistakes, doublets, and

superimpositions in the seismological tradition. Knowledge of ancient dating systems, their equivalents in modern times, the problems raised by various calendar reforms (the Julian, the Gregorian, and that of unified time) is now something, which everyone expects to have. Indeed, there are small computer programs that will carry out a rapid “translation” from one calendar to another. The problem of a correct dating parameter, however, is not just one of correctly establishing the time of origin of the earthquake itself, but also that of dating the many different tremors which make up the overall sequence in large earthquakes. Accurately dating tremors, which preceded the major shock, even though by just a few hours or even minutes, may provide information about the mechanism of its origin. It is also important to be able to distinguish between the effects of separate but chronologically close earthquakes, for they may become superimposed in a single blurred image of a great nonexistent seismic event.

4.3 Intensity: Really So Simple?

Some literature on the historical origins of intensity scales has thrown light on the relationships between the various scales, from Mercalli’s first formulation of 1883 to the latest elaboration of the European Macroseismic Scale (Grünthal, 1998). There have been more than 70 macroseismic scales of one kind or another, almost all using from 10 to 12 grades (see Guidoboni and Ferrari, 2000).

As has been pointed out, macroseismic scales first began to be applied to historical earthquakes with the arrival on the scene of the new generation of computerized catalogs early in the second half of the 20th century, thereby creating a series of problems. Work on solving these problems has not always been much exposed to scrutiny, each interpreter assuming complete freedom to apply their own criteria. The more sensitive and expert researchers have often complained of the excessive subjectivity of what was being done, but no “rules” or “protocols” for observance have ever been offered or requested.

The closing years of the 20th century, however, have witnessed an increasing sensitivity in the use of historical data. In countries like Italy, where historical catalogs are very important, being used even for locating active faults

FIGURE 7 Practical example of how the term “year” indicates different chronological time frames depending on the chronological system used by the sources: the correspondence is shown between the contemporary calendar’s year 1053–1054 and the Byzantine and Islamic year.

(Gasperini *et al.*, 1998), an attempt has been made to work out a sort of formalization of the criteria to be applied, and to throw light on the selection mechanisms which underlie the famous “subjective criteria” (Monachesi and Moroni, 1993; Molin, 1995; Giuffrè, 1995). There has also been a recent attempt to apply fuzzy sets theory to intensity, with some positive results (see Vannucci *et al.*, 1999, 2000, for the 1920 earthquake in Tuscany); but it is only applicable where there is substantial and rich historical documentation. The problem of assigning intensity values to earthquake effects has many implications, and to discuss them here would take us down too long a road. The factors suggest that a historical catalog is a living thing, which can be analyzed, dismantled, “repaired,” and reinterpreted. It provides the base data for calculating seismic hazard and to locate active faults. But if calculations made for purposes of seismic hazard assessment are to be more than statistical exercises, there are a lot of questions to be asked, both from a historical and a seismological point of view.

4.4 Locating Epicenters

Although the definition of an instrumental epicenter is well established in the literature (see Richter, 1958, for example), the same is not true of a macroseismic epicenter. This is mainly due to a typical lack of standardization in macroseismic studies, and to the widely shared opinion that they are in any case unable to provide reliable estimates. Even Richter (1958) stated:

The practice, in the absence of seismographs, of drawing isoseismals and then locating an “epicenter” at the center of the figure should be discontinued. In the majority of cases the instrumentally located epicenter proves to be at one side of the meizoseismal area.

That the macroseismic epicenter is often considerably distant from the instrumental epicenter should come as no surprise, since the two points clearly have a different physical significance. Indeed, whereas the instrumental epicenter corresponds to the projection onto the surface of the earthquake focus (i.e., the point where the rupture originates), the macroseismic epicenter represents in all likelihood the projection of the Braintree of the rupture zone. It has to be kept in mind, however, that the area of effects is always a matter of interaction between a particular earthquake and a habitational system (and therefore always provides us with additional information about the degree of vulnerability of a particular built-up area).

Establishing the location of a macroseismic epicenter is generally speaking not a problem when data are well distributed across the area concerned. But that is not always the case, especially when one wishes to go a long way back in time, or where the area of origin is at sea or in sparsely inhabited areas (a mountain or a large marshy area are usually a problem). In

these cases approximations become rather large. However, the historical background to the area in question will throw light on the status of available information and provide what is necessary to define degrees of uncertainty (Fig. 8).

4.5 Epicentral Intensity and Equivalent Magnitude

The maximum intensity of an earthquake, $I_{\max}$, is often the only parameter that can be related to the energy released by a historical earthquake. In some cases it is indicated as epicentral intensity, I_o , thus presuming that the macroseismic epicenter coincides with the location where maximum effects are observed. This may be acceptable in principle if the intensity has been observed at a single point. When, on the other hand, the location of the epicenter, as described above, is the result of calculating a mean of the coordinates of several points, a different approach must be used, partly because single determinations of intensity are often influenced by local amplification effects and estimation errors which may considerably alter its value.

It is well known, in fact, that the scalar seismic moment (M_0) is a much more significant estimator of the “size” of an earthquake than any definition of magnitude. As Gasperini *et al.* (1999) point out, the main reason for this is that this parameter has a formulation with a specific physical meaning, since it is linked to the dimensions of the source, the amplitude of the coseismic deformation, and the physical characteristics of the material in which the seismogenetic rupture is produced (see Color Plate 18). Thanks to this definition, the value of the seismic moment does not undergo effects of “saturation,” as does occur with magnitude, since its seismological estimate is arrived at by making use of the whole spectrum of the elastic energy irradiated, and not just a small portion. In fact, since the seismological determination of the seismic moment requires digital seismograms, routine estimates of this parameter are available only when digital recording of earthquakes became common in the late 1970s.

5. Earthquake Archaeology

5.1 Enlarging the Span Time

In order to extend the temporal space available for observing seismic activity, or else to make up for the lack of written data, the historical seismologist sometimes has recourse to archaeology. Earthquakes are not a novelty in archaeology, since interest in them goes back at least to the second half of the 19th century. For example, de Rossi (1874) and Lanciani (1918) produced the first interesting observations about earthquake effects on the ancient monuments of Rome; Willis (1928) did the same for Palestine, and Sieberg (1932) for ancient Egypt, pointing out seismic effects at ancient temples, etc.

FIGURE 8 Diagram showing the various steps of analysis by Gasperini and Valensise (2000) from macroseismic data to inferred seismic source.

Earthquakes have attracted particular attention in Mediterranean archaeology, partly because of the existence of important and well-preserved ancient traces of their activity, and partly because of the strong seismicity of the area. Until the 1970s, archaeological earthquake studies were somewhat generalized attempts to find or draw attention to traces of seismic activity, or what were thought to be such traces, in ancient monuments or ruins. Only in the closing decades of the 20th century does one find seismologists taking a greater interest in such matters, and a specific orientation in that direction can be said to have begun only with the studies on Israel by Karcz and Kafri (1978, 1981) and Nur and Reches

(1979). From the last decade of the 20th century onwards, there is evidence of a broader interest in archaeology. One can see this in the specific nature of some conferences organized either directly by geophysicists or jointly with historical seismologists, and archaeologists (Stiros and Jones, 1996; Boschi *et al.*, 1995; McGuire *et al.*, 2000).

However, even in areas such as the Mediterranean, where earthquakes are powerful and frequent, and the possibility of discovering earthquake effects in an ancient building or a whole archaeological site may not be rare, it is not as frequent as one might expect. There are various factors that limit such possibilities: (1) the history and culture of the sites

concerned; (2) the state of preservation of the seismic scenario, or part of it; and (3) the degree to which archaeologists are interested in finding evidence of earthquakes.

Whether or not it is possible to find traces of seismic effects in an archaeological site depends in particular on the economic history of the site and surrounding area at the moment when the earthquake occurred; for if its economy was in a sound or expanding state, it was both possible and obviously desirable to restore and reactivate the damaged habitational and exchange systems, and hence erase any traces of the damage. On the other hand, if the site or settlement network was in a poor economic state, the few available resources would not permit reconstruction *in loco*, and the inhabited area would be completely or partly abandoned. The earthquake/abandonment dynamic is one which affected not only the ancient and medieval worlds, but also marginal areas in much more recent times (see, for example, the case of the 1968 earthquake at Belice in western Sicily, in the “Catalog of Strong Italian Earthquakes” in the attached Handbook CD in Boschi *et al.*, 2000).

5.2 Seismic Indicators in the Archaeological Record

When archaeology is trying to discover traces of earthquakes, one of its central problems is how to define seismic indicators. This is a complex subject with both general and particular aspects, and it has to be assessed within the specific context of an individual excavation. Unfortunately, however, there exists a “seismological common sense” which leads to the selection of elements that may well be the least typically archaeological. Since an earthquake is a phenomenon that always affects an “area” rather than a “point,” it is necessary to apply concepts to which seismologists may be unaccustomed, such as the interpretation of landscape and its transformations.

As items of evidence, earthquake indicators typically have the characteristics and ambiguities of all other kinds of archaeological evidence: the nexus between the depositional output revealed by excavations and the action which brought it into being can be hypothesized or inferred, but it cannot be proved in a deterministic way. As a result, there are only a few cases where the literature has adopted a seismic hypothesis to account for a specific situation in the archaeological record. A common characteristic of these cases is the presence of macroindicators, such as collapses, in structures which can be described from a functional and constructional point of view as “prestige buildings,” such as villas, baths, and sacred places of the late imperial age. In most of these cases, moreover, the earthquake is assumed to have occurred after abandonment of the site, for it is easier to find indicators of seismic activity where human reaction to seismic damage has not involved restoring the topography and structure of the site. We feel, however, that many pieces of seismic evidence

may have been bypassed in this way. For example, data concerning rural settlements and modest buildings regularly escape notice, even though they were characteristic of extra-urban territorial organization in classical Greek and Roman times. The same is true of the various ways in which society reacted to seismic disasters from an economic and recovery point of view.

This complexity requires a few exclusively stratigraphic remarks. The existence of elevated sites introduces the problem of the downslope displacement of archaeological material as a result of erosion and deposition. Secondary deposits of this kind show the need for a careful analysis of possible earthquake effects on slopes. The same may be said of deformation and movement in architectural structures, such as leaning walls and sloping floors, when buildings are situated on steep slopes or areas subject to landslides. A building’s resistance to ground movement is obviously conditioned not only by its own structure, but also by the nature of the ground itself. The frequency of structural deformation in monumental buildings (theatres, for example) highlights the problem of lack of solidity in basal strata and the unstable nature of the backfill on which they were built.

5.3 The Dating of Archaeological Indicators from Written Sources: the Birth of “Seismic Monsters”

Among archaeologists who are interested in earthquakes, fairly widespread use is made of a technique that might be called “combinatory,” because it makes use of written sources in order to date archaeological evidence. From an epistemological standpoint, this leads to a sort of circular argument in which written sources provide an absolute chronology and support the archaeological sources, which are in turn offered as evidence of local seismic effects caused by a specific earthquake which is mentioned in reliable written sources, but in which there is no mention of damage at the archaeological sites in question. Earthquake damage is thus imposed on the seismic scenario in a rather unscientific and rarely explicit way.

The methodological reason why the combinatory approach cannot be adopted is as follows: written sources and archaeological sources are based on two conceptually different timescales, resulting from the diverse nature of the two types of data concerned. The former may make reference not only to the year, month, and day when the historical event they describe took place, but even to subdivisions of a day, such as hours; the latter make reference to a timescale which has the year as its base, but acquires an identity only within the stratigraphic sequence in which the archaeological record is contained, that is to say only within a span of years. This method of dating archaeological earthquakes by means of written sources has created some seismological “monsters.” That is to say, the effects of several earthquakes perhaps some

distance apart have been drawn together into a single event. The most famous case is that of the earthquake of 21 July 365 AD to the southeast of the island of Crete, which has been associated with numerous cases of damage caused by different earthquakes occurring in the space of a few decades across the whole Mediterranean area from Cyprus to Sicily and North Africa (Ambraseys, 1965; Di Vita, 1990; Bernabò Brea, 1997). The conceptual problem behind this use of archaeological sources lies, as we have already pointed out, in the habit of dating seismic indicators in an absolute way by anchoring them to a written text.

5.4 Where is Archaeoseismology Going?

Although it offers a host of interesting data and stimulating suggestions, archaeoseismology is not yet a discipline in the strict sense of the term, not only because its interpretations are often not based on a rigorous and transparent method, but also because there does not yet exist a numerically significant community which recognizes itself as seismic archaeology, “takes a stand,” and “gives its approval” to methods and results. What we have are simply a few individual scholars. As in the case of historical seismology, nobody teaches it, and it has no recognized academic positions or schools. Nowadays it could be described simply as an important research exercise. So the literature relies for the most part on the goodwill of authors and reviewers who are usually excellent seismologists, geophysicists, and geologists, but often lack relevant experience and archaeological qualifications. But we cannot ignore the fact that research of this kind does happen, and does produce data. Perhaps we can correctly define seismic archaeology as an area where questions about historical seismology are asked, and archaeological sources are used to supply an answer. The usefulness and quality of the results produced by research of this kind, even when it is in essence multidisciplinary, are at the moment proportional to the quality of the dialogue being initiated between archaeologists and those who study earthquakes, and to the correct formulation of the questions to which an answer is being sought.

6. General Conclusions and New Questions

Let us attempt an assessment of the complex research field of historical seismology. It appears to be growing strongly and with increased potential, in spite of its problems (but what research field is free of problems?). As this brief excursus perhaps illustrates, the quality of the research concerned is a function of the clarity and transparent nature of the method of investigation, and of the systematic way in which data are acquired and data sets formed. A substantial refinement in the quality of the historical data produced in the last 20 years has been responsible for increasing the seismological significance

of the data themselves, thereby also promoting more refined methods of calculating “traditional” parameters, and also suggesting new applications. More complex and detailed maps of effects have revealed the irregular nature of earthquake propagation as opposed to the regularity that tended to be emphasized by the use of isoseisms. These results have been enhanced by the application of new technologies to the data, and have stimulated a critical attitude that has led to the progressive abandonment of simplificative or simplistic geometries of what was known in the 1970s as the “macroseismic field.”

It is clear that Italy has become a testing ground of considerable importance for new methodologies (see the complex introduction to “Catalogue of Strong Italian Earthquakes” Boschi *et al.*, 2000, with several contributions on this topic) both because it has had a large number of strong earthquakes within a context of extraordinary documentary wealth, and because there has been substantial investment in the field of historical seismology.

There are many problems to be grappled within a comprehensive way and one shared by countries which use historical earthquake catalogs. They include the explicit adoption of generally accepted interpretative rules, the use of transparent processes of parameter interpretation, and elaboration, right from the recording of basic data and the drawing up of intensity estimates. The establishment of a research “protocol” acceptable to the experts might also make it possible to enhance the quality of the various current national earthquake catalogs, and lead on to widespread improvements.

Finally, there seems to be a need for stable collaboration between countries in the collection of basic data, even though they are often a great distance apart. The countries of North Africa and Latin America are a good example, for they have many important documentary sources preserved in European cities. And then there are the former Soviet republics, whose many important sources are now in cities which are difficult to reach, or situated in areas of political conflict.

Because of its ability to investigate the cultures of the past and create a sort of *trait d'union* between past and present, historical seismology provides data which are also suitable for scientific popularization purposes and social information. It produces a “deposit” of scientific information which can convey to resident populations the extent to which the characteristics of the environment in which they live are stable, and can be used to good effect in seismic risk reduction programs.

Earthquake History: Some Examples

48.1 Introduction

W.H.K. Lee

US Geological Survey, Menlo Park, California, USA (retired)

Even before civilization began, earthquakes have caused much suffering to mankind. In order to mitigate earthquake hazards, it is important to learn from past earthquakes. Although seismograms comprise the basic observational data for earthquake studies, instrumental records exist only for slightly over 100 years. We must, therefore, depend on recorded history and related materials to extend our knowledge about the past earthquakes before the instrumental era. Since instrumental coverage of the world was not adequate until the establishment of the WWNSS and the ESSN in the early 1960s (see Chapter 17 by Lee), recorded history and related materials are still critical in many areas of the world up to about 1963. For convenience, we use “historical” to mean the era before 1963.

Because seismograms before 1963 were difficult to access, an effort was made to archive “historical” (i.e., pre-1963) seismograms in the late 1970s and early 1980s. Unfortunately, this effort was not successfully completed due to the lack of continued funding. A symposium on “Historical Seismograms and Earthquakes” was held on 27–28 August 1985, during the General Assembly of the International Association of Seismology and Physics of the Earth’s Interior (IASPEI) in Tokyo, Japan, to document what we had accomplished. Sixty papers were presented, of which 51 papers were submitted for publication in a Proceedings volume, “Historical Seismograms and Earthquakes of the World”, edited by W.H.K. Lee, H. Meyers, and K. Shimazaki, Academic Press, San Diego, 1988. This volume is placed as a PDF file on the attached Handbook CD, under the directory \48.1Lee2.

In particular, this Proceedings volume contains the following papers, which may be of interest to readers of earthquake history. They are listed below in the order as they appeared in the Proceedings volume, and interested readers can read them on the attached Handbook CD as noted above.

1. “Historical Materials of Chinese Earthquakes and Their Seismological Analysis” by Yushou Xie
2. “The Anatolian Earthquake of 17 August 1668” by N.N. Ambraseys and C.F. Finkel
3. “An Analysis of the Eastern Mediterranean Earthquake of 20 May 1202” by N.N. Ambraseys and C.P. Melville
4. “Preliminary Evaluation of the Large Caracas Earthquake 07 of 29 October 1900, by Means of Historical Seismograms” by G.E. Fiedler
5. “Evaluation of Damage and Source Parameters of the Malaga Earthquake of 9 October 1680” by D. Munoz and A. Udias
6. “Studies of Earthquakes on the Basis of Historical Seismograms in Belgium” by M. De Becker and T. Camelbeeck
7. “Documenting New Zealand Earthquakes” by G.A. Eiby
8. “Historical Earthquakes and the Seismograms in Taiwan” by Pao Hua Lee
9. “Historical Earthquakes of Thailand, Burma, and Indochina” by S. Prachuab
10. “Earthquake History of California” by T.R. Toppozada, C.R. Real, and D.L. Parke
11. “Study of Historical Earthquakes in Japan (2)” by Tatsuo Usami
12. “Studies of Philippine Historical Earthquakes” by R.G. Valenzuela and L.C. Garcia
13. “The History of Earthquakes in the Northern North Sea” by R. Muir Wood, G. Woo, and H. Bungum

This chapter includes four brief subchapters as examples of earthquake history. Their full manuscripts are also given on the attached Handbook CD.

48.2 California Earthquakes of $M \geq 5.5$: Their History and the Areas Damaged

Toussou Topozada and David Brannum
California Division of Mines and Geology, Sacramento, USA

California's documented history started around 1800 with fragmentary writings from the Franciscan missions between San Diego and Sonoma. Two earlier significant earthquakes were also recognized. In 1700 a giant $M \sim 9$ earthquake on the Cascadia subduction zone between Eureka and Vancouver was inferred from studies of Indian legends, submerged soils and trees, and tsunami heights documented in Japan (Satake *et al.*, 1996). In 1769 the Portola expedition felt earthquakes for about a week in the Orange–Los Angeles county area. Their descriptions suggest a $M \sim 6.5$ earthquake and aftershocks in the local area, or a larger earthquake on the San Andreas fault system ~ 80 km to the east.

Since 1850, 167 earthquakes of $M \geq 6$ have been documented in California and its border regions (bigger border region than in Fig. 1a). At least 91 occurred in the preinstrumental period before 1932, the record being incomplete before about 1910. Seventy-six were located since 1932 with varying seismographic control, indicating an average rate of about 1.1 per year, or 0.9 y between events.

In the vicinity of the border with Mexico, the Imperial and Southern San Jacinto faults region has been active before and after 1932. The San Andreas fault system was very active north west of this vicinity before 1932, but since 1932 only had a few events near Desert Hot Springs, Parkfield, and the San Francisco Bay area (Fig. 1a). The main San Andreas fault south of the 34th parallel has had few earthquakes since 1800.

Five of the largest ($M \sim 7$ or larger) earthquakes since 1800 have occurred on the San Andreas fault (Fig. 1a). The most recent occurred in 1989 near Loma Prieta. The other four events occurred in two pairs of overlapping zones, in Southern California in 1812 (8 and 21 December) and 1857, and in Northern California in 1838 and 1906 (Fig. 1b). The 1812 and 1838 earthquakes generated effects that were generally as strong in their regions as were the effects of the overlapping 1857 and 1906 earthquakes, respectively. Earthquakes that

occur only a few decades apart are difficult to differentiate in fault trenches because of the limitations in stratigraphic resolution and radiocarbon dating. Thus, pairs of overlapping major events on the San Andreas fault such as 1812/1857 and 1838/1906 may be more common than paleoseismology would indicate.

The 630 km length of the San Andreas fault between San Francisco and Cajon Pass ruptured in the 1838 and 1857 earthquakes, except for about 75 km between Bitterwater and San Juan Bautista (Figure 1). Probable aftershocks of the 1838 event occurred in 1840 and 1841 near San Juan Bautista. Foreshocks and aftershocks of the 1857 event occurred near Bitterwater until 1885 (Topozada *et al.*, 2002). Near Parkfield, 40–70 km southeast of Bitterwater, $M = 5.5$ or greater earthquakes have occurred from the 1870s to the 1960s. In the total Bitterwater to Parkfield zone bracketing the northern end of the 1857 rupture, the seismicity and moment release have decreased steadily since 1857, and have tended to migrate southeastward with time.

A major earthquake was thought to have occurred on the Hayward fault in 1836, until Topozada and Borchardt (1998) determined that it was a smaller event located between Monterey and the San Jose–Santa Clara area, far from the Hayward fault. The $M \sim 7$ Hayward fault earthquake of 1868 was of comparable size to the 1989 Loma Prieta event. The 1868 earthquake was preceded by 13 y in which twelve $M \geq 5.5$ earthquakes occurred within 60 km of the Hayward fault, and was followed by 13 quiet years when only one $M \geq 5.5$ Bay area earthquake occurred, that was not an aftershock. Similarly, five $M \geq 5.5$ Bay area earthquakes occurred in the 10 y leading up to the 1989 Loma Prieta event, which has been followed by 12 quiet years so far. The post-1868 Hayward earthquake quiescence suggests that the present Bay area quiescence following the 1989 Loma Prieta event may not last much longer than 13 years (Topozada *et al.*, 2002).

FIGURE 1 (a) $M = 6.0$ and greater California earthquakes, 1800–2000. Triangles indicate the 68-y instrumental record and circles indicate the 132-y preinstrumental record. Faults: SA, San Andreas; Hay, Hayward; SJ, San Jacinto; Imp, Imperial. (b) San Andreas fault ruptures in the overlapping 1812/1857 and 1838/1906 regions.

Toppozada *et al.* (2000) and Toppozada and Branum (2002) provide maps and lists of about 400 $M \geq 5.5$ earthquakes, of which more than half occurred before 1932. The pre-1932 epicenters and magnitudes were estimated predominantly by interpreting and mapping the reported earthquake effects

and comparing them with those of instrumented earthquakes (e.g., Toppozada *et al.*, 1981, with additions and revisions). Moment magnitude (M_W) is used when available, otherwise surface-wave magnitude, local magnitude, or magnitude derived from the size of the areas shaken at various intensities

TABLE 1 Significant California Earthquakes ($M \geq 6.5$ and/or Destructive)

Date ^a	Latitude	Longitude	M	Region	Loss of Life and Property
18121208	34.37?	-117.65?	~7.3	Orange County, Los Angeles, Wrightwood	40 deaths at San Juan Capistrano
18121221 ^b	34.75?	-118.60?	~7.1	Los Angeles, Ventura, Santa Barbara	1 death
18380600	37.30?	-122.15?	~7.4	San Francisco to San Juan Bautista	Damage from San Francisco to Monterey
18570109	36.20	-120.80	7.9	Great Fort Tejon earthquake	1 death, damage from Monterey Co. to San Bernardino Co.
18651008	37.20	-121.90	6.5	Santa Cruz Mountains	\$500 000 in property loss
18681021	37.70	-122.10	7.0	Hayward Fault	30 deaths, \$350 000 loss
18720326	36.70	-118.10	7.4	Owens Valley	27 deaths, 56 injuries, \$250 000 loss
18731123	42.00?	-124.20?	6.9	Crescent City regoin	Damage in California–Oregon border area
18900209	33.40	-116.30	6.8	San Jacinto fault?	Little damage
18920224	32.55	-115.65	7.3	Laguna Salada, Baja California	Damage San Diego to Imperial Valley
18920419	38.40	-122.00	6.6	Vacaville	1 death, \$225 000 loss
18980331	38.20	-122.50	6.4	Mare Island	\$350 000 loss
18980415	39.20	-123.80	~6.7	Fort Bragg–Mendocino	Damage from Fort Bragg to Mendocino
18991225	33.80	-117.00	6.7	San Jacinto and Hemet	6 deaths, \$50 000 loss
19060418	37.70	-122.50	7.8	Great 1906 earthquake	3000 deaths, \$524 million loss (counting fire damage)
19180421	33.75	-117.00	6.8	San Jacinto	1 death, several injuries, \$200 000 loss
19230122	40.40	-124.90	7.2	Off Cape Mendocino	Destructive in Humbolt Co., strongly felt to Reno
19250629	34.30	-119.80	6.8	Santa Barbara	13 deaths, \$8 million loss
19271104	34.60	-120.90	7.1	40 km west of Lompoc	Damage in Santa Barbara and San Luis Obispo counties
19330311	33.70	-118.00	6.4	Long Beach	115 deaths, \$40 million loss
19400519	32.73	-115.50	7.0	Imperial Valley	9 deaths, \$6 million loss
19520721	35.00	-119.02	7.3	Kern County earthquake	12 deaths, \$60 million loss
19541221	40.93	-123.78	6.6	East of Arcata	1 death, several injuries, \$2.1 million loss
19710209	34.41	-118.40	6.6	San Fernando	65 deaths, 2000+ injuries, \$505 million loss
19791015	32.61	-115.32	6.5	Imperial Valley	91 injuries, \$30 million loss
19801108	41.12	-124.67	7.4	West of Eureka	6 injuries, \$2 million loss
19830502	36.23	-120.31	6.4	Coalinga	\$31 million loss, 1 death, 47 injuries
19840424	37.31	-121.68	6.2	Morgan Hill	\$8 million loss
19871001	34.07	-118.08	6.0	Whittier Narrows	8 deaths, \$358 million loss
19871124	33.01	-115.85	6.6	Superstition Hills	\$3 million loss
19891018	37.04	-121.88	6.9	Loma Prieta	63 deaths, 3757 injuries, \$6 billion loss
19920425	40.33	-124.23	7.2	Cape Mendocino area	356 injuries, \$48.3 million loss. Two $M = 6.6$ aftershocks next day
19920628	34.20	-116.44	7.3	Landers	1 death, 402 injuries, \$91.1 million (losses include Big Bear earthquake 3 h later)
19940117	34.21	-118.54	6.7	Northridge	57 deaths, 9000+ injuries, ~\$40 billion loss
19991016	34.60	-116.27	7.1	Hector Mine	Minimal injuries and damage due to sparse population

Loss from Stover and Coffman (1993).

^aThe date is given as year, month, day (Greenwich).

^bProposed epicenter on or near San Andreas fault (Toppozada *et al.*, 2002).

is used. Toppozada and Branum (2002) have developed new analytical relationships between M_W and the areas shaken at or above Modified Mercalli Intensity [MMI] V, VI, and VII. They also list all available estimates of magnitude for earthquakes having more than one estimate. The earthquake information from 1932 onward is, with a few identified exceptions, from the catalogs of Caltech and UC Berkeley, supplemented by USGS information after 1969.

Table 1 lists the significant California earthquakes since 1800, generally of $M \geq 6.5$, and the resulting losses. The greatest losses to lives and property occurred in the great 1906 San Francisco earthquake, and in the $M = 6.4$ to $M = 6.9$ urban earthquakes in 1933 Long Beach, 1971 San Fernando, 1989 Loma Prieta, and 1994 Northridge. Smaller losses resulted from major $M \geq 7$ earthquakes occurring before the population

growth in California that followed the 1849 Gold Rush, or in regions that are still sparsely populated. Toppozada *et al.* (2000) and Toppozada and Branum (2002) show maps of the areas shaken at MMI VII or greater, which is the threshold of damage to weak buildings. Such damage has occurred since 1800 at least six times in each of the Eureka, San Francisco Bay, and Los Angeles regions.

48.3 The Historical Earthquakes of India

S.P. Satyabala

National Geophysical Research Institute, Hyderabad, India

1. Introduction

The historical earthquakes of India are important for understanding seismicity in and around India. Documentation of macroseismic effects of earthquakes of India is available for the five great earthquakes (1819, 1897, 1905, 1934, and 1950) and several other major earthquakes. There has been a quiescence of major ($M_s \geq 7.5$) earthquakes in this region during the second half of the 20th century (Satyabala and Gupta, 1996), causing concern for seismic hazard in the region (e.g., Khattri, 1987; Bilham *et al.*, 1995; Yeats and Thakur, 1998). [See Editor's Note.] Great and intermediate-to-small earthquakes form two parallel belts of seismicity along the Himalayan arc. As proposed by Seeber and Armbruster (1981), two major seismogenic faults form concentric arcs along the Himalayan arc: a detachment thrust on which the major/great earthquakes occur and a steeper dipping thrust on

which moderate earthquakes occur. Strong evidence that the great earthquakes occurred on a shallow dipping (quasi-horizontal) thrust plane or detachment is the consistent absence of primary faulting for all these earthquakes and the very large area over which the strongest macroseismic effects are manifest.

2. The CD Appendix

The CD appendix includes summaries of the macroseismic effects of some historical earthquakes of India (listed in Table 1 and shown in Color Plate 19). Primary source materials are the Memoirs and Reports published by the Geological Survey of India that report investigations carried out immediately or soon after the earthquake. The material presented for each earthquake includes salient features of the results, summary

TABLE 1 Historical Earthquakes of India [Presented in Detail on the Attached Handbook CD (Text and Graphics)]

S.no.	Earthquake		Location		M_s	Intensity Scale	Maximum Intensity	Main Reference

10	12 June 1897	Shillong	91	26	8	ME	X	M/GSI, vol. XXIX & XXX
11	10 January 1869	Cachar	92.7	26	7.5	MMI	VIII–X	M/GSI, vol. XIX
12	16 June 1819	Cutch	69	24	7.8	MMI	X+	M/GSI, vol. XXVIII and XLVI (Part II)

Note: Brief descriptions are also available on the CD for the 1762 Arakan, 1803 Mathura, 1816 Gangotri, 1833 Nepal, 1839 and 1858 Burma, 1885 Kashmir, 1885 Bengal, 1954 Manipur–Burma, 1956 Burma earthquakes and others.

Abbreviations: M/GSI, R/GSI = Memoirs/Records of the Geological Society of India.

descriptions, and graphic interpretation of the macroseismic effects within each isoseist (movements felt and sounds heard; effects on terrain, e.g., landslides, liquefaction phenomena and faults; and effects on manmade structures, e.g., buildings, roads, and railways). Intensity scales are adopted from the original sources (mostly Rossi-Forel or the Mercalli scale). As discussed in the CD appendix, major limitations in delineating the isoseismals are inaccessibility for investigation and insufficient information across the mountain ranges. An effort has been made to describe/summarize all the macroseismic effects irrespective of whether they are common or rare.

3. Conclusions

The great earthquakes were felt over large areas in India and each individual earthquake produced different macroseismic effects on an unusual scale. The intensity displayed by the 1905 Kangra earthquake contrasts with the other three earthquakes of the Himalaya (1897, 1934, and 1950) that produced cataclysmic effects such as fault-scarps, destruction of railway tracks and iron girder bridges, the bending and snapping of trees, fissures and sand/water vents. The 1905 Kangra earthquake occurred on segments of the sub-Himalaya characterized by dun valleys and by anticlines at the Himalayan front, and is inferred to have occurred on a blind thrust and expressed at the surface as a fold.

The 1934 Bihar–Nepal earthquake, notable for producing the “slump belt” and spectacular sand and water vents, occurred in segments of the central Himalaya characterized by imbricate thrusts. The 1950 Assam earthquake, which caused landslides on an enormous scale, occurred near the Eastern Syntaxis of the Himalaya. The 1905 Kangra, 1934 Bihar–Nepal and 1950 Assam earthquakes occurred on the detachment surface between the Indian shield and Himalayan rocks. The 1897 Shillong earthquake occurred in a region south of the Himalayan arc and produced a bell-shaped meizoseismal area, the strongest effects within which furnished the principal model for the highest grade XII of the Modified Mercalli Intensity Scale (Richter, 1958). The 1819 Kutch earthquake, which produced the “Allah Bund,” a ~60 km-long fault scarp with a total vertical displacement of 7–9 m, occurred within the stable continental region of India.

The fact that there is a quiescence of major/great earthquakes in the present modern instrumental era of seismology renders the information available in the Memoirs/Records of the Geological Survey of India invaluable for any possible assessment of earthquake hazard in and around India. These earthquakes best illustrate the possible macroseismic effects

and the scale on which these effects could be displayed if earthquakes of such a magnitude should recur.

Acknowledgments

I thank Dr Harsh K. Gupta, Director, National Geophysical Research Institute, India, for his encouragement during this work. I thank Dr Lee and three anonymous reviewers for critical comments that improved this contribution.

Editor's Note

Due to space limitations, an Appendix containing 13 chapters of historical earthquakes of India is placed on the attached Handbook CD, under the directory \48.3Satyabala. A disastrous earthquake of magnitude 7.6 occurred on 26 January 2001 near Bhuj (Gujarat State) in western India. About 20,000 persons were reported dead and an economic loss of about US\$5 billion was estimated (see *Seism. Res. Lett.* **72**(3), 2001.)

48.4 Historical Earthquakes in Japan

Tatsuo Usami

The University of Tokyo, Tokyo, Japan (retired)

1. Introduction

Japan is one of the most earthquake-prone countries in the world. The earliest earthquake on record is one that hit Yarnato (now Nara Prefecture) on 23 August 416 AD, but no record of the damage has been found. Next oldest is another one that struck Yarnato on 28 May, 599; extant documents indicate that it caused houses to collapse. It would appear to have registered about magnitude 7 on the Richter scale. Since then, there have been 796 destructive earthquakes, or ones causing damage, in the 1397 years up to 1995. In the 128-y period since the Meiji Restoration in 1868, when Japan's modernization began, there have been 453 destructive earthquakes (Usami, 1996); an annual average of 3.5 events.

2. The Study of Historical Earthquakes in Japan

When efforts to modernize the state commenced with the Meiji Restoration in 1868, there was still little information about which areas of the country were frequently afflicted by earthquakes and which were less prone. Observations using seismographs began to be made, but they were too poor both in number and efficiency. Inevitably, the study of earthquakes had to begin by looking into records of past earthquakes and related matters in historical documents. These efforts at material collection are outlined below. Early studies were made by Ichizo Hattori, Edmund Naumann, and John Milne. These studies did indeed provide valuable data for modern seismological studies, which at the time were in their infancy. However, since they all referred to a relatively small range of materials and thus had a limited number of earthquakes to study, their results could not be treated as conclusive. A full-scale study would require a new start and a more comprehensive approach.

2.1 Comprehensive Compilation (Phase I)

In 1892 the Imperial Earthquake Investigation Committee was organized with, as one of its aims, the compilation of data on historical earthquakes. The committee put Minoru Tayama in charge of this task in 1893, and efforts got going under the supervision of Seikei Sekiya. Tayama made an extensive search of historical documents, archives, diaries, and other materials, culminating in publication of the "Catalog of Historical Data on Japanese Earthquakes" (Tayama, 1899). This covered 1896 earthquakes in the period 416–1864, and gave tables in which the date, time, location, and strength of each earthquake was recorded and reference materials were listed. Based on this catalog, Fusakichi Omori compiled a list of 222 major earthquakes, including those that occurred in the Meiji era (1868–1912). In 1904, Tayama published the 1201-page "Historical Data on Japanese Earthquakes" (Tayama, 1904). This was a chronicle of the original documents relating to earthquakes between 416 and 1865, and provided a model for the later "New Collection of Materials for the History of Japanese Earthquakes." Tayama left his commission in 1902 prior to publication of this report.

In 1913, Omori used Tayama's data to examine 95 pre-1876 earthquakes and determine their hypocenter, the area suffering seismic motion, and the occurrence of aftershocks, tsunami, damage etc. (Omori, 1913). Further, in 1919 he prepared a summary table (Omori, 1919) covering the period from the beginning of Japan's recorded history up to 1918.

2.2 Comprehensive Compilation (Phase II)

Efforts at the systematic compilation of earthquake data then came to a halt until 1928, when Kinkichi Musha began work under the supervision of Torahiko Terada at the Earthquake Research Institute. Commissioned by the institute, Musha dedicated himself to the task of compilation and published his results between 1941 and 1951 as expanded and revised

editions of Tayama's "Historical Data on Japanese Earthquakes." His publications consisted of three expanded and revised volumes of "Historical Data on Japanese Earthquakes" (Earthquake Prevention Council, Ministry of Education, 1941–1943), and a volume of "Historical Data on Japanese Earthquakes" (Musha, 1949). These publications total 4000 pages and deal with around 6400 earthquakes.

2.3 Comprehensive Compilation (Phase III)

After Musha, a further period ensued in which no systematic effort at compilation took place. Work only resumed about 20 years ago, when it was decided to focus on the collection of historical materials from which Tayama or Musha did not, in the end, quote. These included materials related to volcanic eruptions and earthquakes in Taiwan and Korea, and to phenomena not clearly identified as related to earthquakes. Generally, they were left out merely because of the huge volume of the documents.

With a budget from the government and assistance from Japan Electric Association, enthusiastic efforts began to recompile these materials. This led to the publication of "New Collection of Materials for the History of Japanese Earthquakes" starting in 1980. A total of 21 volumes of documents had been issued by 1994, filling about 16000 pages (Usami, 1980–1994). The foundations for studies of historical earthquakes in Japan were thus almost complete. The work of putting all this material into print continues.

3. Examination of Historical Materials

3.1 Interpretation

As mentioned above, records of earthquakes in Japan are in a variety of forms including official historical documents, private historical materials, records, chronicles of local history, letters, and dossiers. All are written by brush on Japanese paper. The first task confronting analysts is to interpret them, which essentially means rendering them into modern script. This work requires a knowledge of archaic terms and writing styles together with certain special training.

3.2 Seismic Intensity Distribution

The second stage of the examination is to sort the various interpreted data chronologically. At this stage records with the same time and locality are considered to belong to the same earthquake. Some earthquakes may have just a single line mention, whereas major ones have descriptions extending over a thousand pages or more.

Archaic documents only include such data as the feelings caused by the ground motion and the damage it caused, as well as related episodes. The seismic intensity at various affected locations is judged mainly from descriptions of the damage, crustal deformation, tsunami, and ground motion.

Intensity is worked out according to the current scale. To do this, it is first necessary to prepare a table of intensities (Usami, 1986) applicable to historical earthquakes, since structures used to be more vulnerable than they are now. On the other hand, the human sensitivity to ground motion remains unchanged. It is also possible to determine seismic intensity comparatively accurately from the damage to ancient structures, such as famous temples and castles, which remain to this day. In the most difficult cases, for example, where nothing that suffered damage remains, as is the case for private houses, the estimation process relies on the experience of those involved.

Once a distribution of seismic intensity is determined by estimating the intensity at various points, the magnitude is estimated and the epicenter determined from the strong motion area (the area within which the intensity is IV, V, and VI on the Japanese scale) using an empirical equation.

This determination of hypocentral characteristics needs to be made by comparison with similar modern earthquakes.

3.3 Trends in Destructive Earthquake Activity

Where an earthquake yields only a few data points, the hypocentral characteristics cannot be determined by the above process, so clearly such analysis is only possible in the case of earthquakes that caused damage. Figure 1 shows the number of destructive earthquakes by decade from the beginning of Japan's recorded history up to 1995. Note that the apparently increasing occurrence of earthquakes results from the ever-improving quality and quantity of historical materials as we approach the present. Although Figure 1 does not show an accurate record of the natural phenomenon itself, it is possible to read the rough trend of seismic activity rising and falling from this type of data.

The number of recorded destructive earthquakes began to rise after around the year 1600. This was because the Edo Shogunate government came into being around that time and produced large numbers of official documents. It also marked the start of a long period of political stability, so the documents have remained intact until the present. A surge in the number of destructive earthquakes is observed starting around 1880, when seismographs began to be used and modern methods of precision recording began. Nowadays, destructive earthquakes occur three to four times a year, but the damage caused is mostly minor. Medium-scale and major damaging earthquakes occur a few times a decade or so.

FIGURE 1 Trends in the number of destructive earthquakes by decade in Japan (599–1995).

4. Building a Picture of Historical Earthquakes

In investigating historical earthquakes, it is essential to build up a picture of the event by answering such questions as: Was the hypocenter deep or shallow? Was there a tsunami? Was it an inland earthquake? Was it a major event, or of what magnitude was it? Did a fault appear? This work of developing a picture of the Earthquake progresses in parallel with the effort to determine the hypocentral characteristics mentioned above. In the full manuscript, on the attached Handbook CD, three cases are given to illustrate this process.

5. Social Effects of Earthquakes

Major earthquakes often leave scars of various types on individuals and regions. They wreak havoc over extensive areas of political, social, and economic life, and often have socio-psychological consequences. Although this must have been true of earthquakes that occurred centuries ago, no historical documents have been collected to back up this assertion, nor has any research been done on this question. Just one or two episodes and recorded cases are available for study.

In the full manuscript, two cases of forced migration imposed by earthquakes are discussed. The aim is to shed some light on how seriously earthquakes can affect a society and how difficult it is to prepare for such disasters.

6. Conclusion

The task of summarizing all studies of historical earthquakes in Japan is a difficult one. This chapter simply attempts to provide a taste of such studies by describing some case studies of how an accurate picture of an earthquake can be developed. Two cases of mass migration are also dealt with, highlighting some of the social effects of earthquake. The study of historical earthquakes from the viewpoint of society, as shown in this paper, lags behind other fields, and this is an issue to be addressed in the future.

48.5 Historical Earthquakes of the British Isles

R.M.W. Musson

British Geological Survey, Edinburgh, United Kingdom

1. Introduction

The British Isles are not a part of the world generally associated in the public mind with earthquakes, and it may come as a surprise that there is so much material for study on the subject of British seismicity. The reasons for this are twofold; in the first case, earthquakes severe enough to cause minor damage do occur from time to time, which means that seismic risk is not completely negligible. Secondly, the intellectual history of Britain has meant that for a long period there have been people interested in recording or studying details of local earthquakes.

This can be seen if one looks at the history of the study of British earthquakes. This can be traced back a very long way; the earliest attempt to compile a chronological list of British earthquakes is that by Fleming (1580). It is no coincidence that 1580 also happens to be the date of a relatively large earthquake in the Dover Straits, which was strongly felt in London, and killed two children. Throughout this subchapter phrases like “relatively large” must be understood as being in the context of British seismicity; the 1580 event had a magnitude of around $5.8 M_L$.

London, then as now, was the intellectual center of the kingdom and the location of the bulk of what passed for what would now be termed the media. The earthquake of 1580 stirred up much general alarm and led to the production of numerous pamphlets on the subject of earthquakes rushed out to satisfy the sudden public interest in the subject (Ockenden, 1936). Fleming’s purpose in writing was not scientific; although he makes passing reference to theories of earthquake causation (chiefly the classic Aristotelian hypothesis of winds trapped beneath the earth) his main objective in writing is to present earthquakes as warnings from God.

2. Earlier Studies

Truly scientific studies of British earthquakes started in the second half of the 17th century, when the establishment of the

Royal Society in 1666 provided a focus for scientific investigation, with the *Philosophical Transactions* as a ready medium for the publication of data and results. Accordingly, the collection and publication of felt reports of the 1666 Oxford earthquake by Boyle and Wallis (Boyle, 1666; Wallis, 1666) appears to be the first recognizable scientific macroseismic study of an earthquake in modern times. A number of these early studies exist, either in print or in manuscript. The English Channel earthquake of 1734 caught the interest of the Duke of Richmond, a member of the Royal Society, who encouraged a local physician to collect reports of the earthquake; although a summary report was published (Richmond, 1738) the original manuscripts still survive (Neilson *et al.*, 1984). These were not particularly large or damaging earthquakes; the low level of seismicity in Britain has always meant that small earthquakes felt at intensities of 4 or 5 EMS (European Macroseismic Scale; Grünthal, 1998) have been considered as notable and newsworthy events. (Note: the EMS used here is a 12° intensity scale similar in equivalence to other 12° scales in general use. The text is available at <http://www.gfz-potsdam.de/pb5/pb53/projekt/ems/index.html>).

Another boost to interest in British earthquakes was provided by two small shocks (2.6 and $3.1 M_L$) on 8 February 1750 and 8 March 1750 with epicenters in central London. This caused a repeat of the pattern of 1580, i.e., a sudden public interest in earthquakes and a rush of publications to meet this interest. Some of these quickly-turned-out works are of little value; the best of the catalogs that resulted is probably that by Zachary Grey, published as “A Chronological and Historical Account of the most Memorable Earthquakes . . . By a Gentleman of the University of Cambridge” (Grey, 1750). It is often mentioned how scientific interest in earthquakes in Europe received a strong boost from the occurrence of the disastrous Lisbon earthquake in 1755; but in Britain this boost really occurred five years earlier, from these two small London earthquakes, a point noted by Kendrick (1956).

In the 19th century the focus for the study of British earthquakes shifted from the Royal Society to the British

Association for the Advancement of Science (BAAS or simply BA). The occurrence of an earthquake swarm near Comrie, Perthshire, led to the formation of a scientific committee for the study of earthquakes, formed under the auspices of the BA and headed by David Milne (later Milne-Home) and James Forbes. A full account of the work of this committee and its significance in the history of seismology is beyond the scope

of this discussion, and the reader is referred to Musson (1993). However, as part of his activities, in addition to collecting numerous felt reports of the larger shocks in the Comrie sequence (especially the largest: 23 October 1839 $4.8 M_L$), Milne (1842–1844) also compiled a descriptive catalog of previous British earthquakes, the largest such catalog up to this date. This is about the start of the period of the great

FIGURE 1 Map showing earthquakes in the British Isles of magnitude 4.0 M_L or greater from 1382 to 1999.

earthquake catalogs such as von Hoff (1840) and Mallet (1852–1854), which include British earthquakes. Perrey's annual catalogs contain British events and he also published a regional catalog for the British Isles (Perrey, 1849).

The second half of the 19th century saw the rise of the amateur scientific society. These “field clubs” were a recreational focus for amateur naturalists, meteorologists, etc., and usually published their own journals where data could be presented. Local earthquakes, when they occurred, formed a natural subject for study, and some very substantial data sets were published in this way, the best-known being the book-length account of the damaging 22 April 1884 Colchester earthquake ($4.6 M_L$) by Meldola and White (1885).

3. Modern Studies

The most important amateur contributor to British seismology was Charles Davison, a mathematics teacher, who from 1889 to 1926 single-handedly ran a macroseismic monitoring program in the United Kingdom. In 1896 he started work on a catalog of British earthquakes, which was finally published in 1924. This work (Davison, 1924) contains the first attempt to present a quantitative account of British seismicity, using an intensity scale of Davison's own devising but loosely based on the Rossi–Forel scale. Davison also attempted some critical regard to sources, for example, rejecting a series of spurious earthquakes published first by Thomas Short (1749) as without historical foundation. However, Davison was not a historian, and had a hard time (for example) with the confused dates of medieval earthquakes found in the various chronicles.

Davison's catalog remained the standard source on historical British earthquakes for the next 50 y or so. A first attempt to compile a numerate catalog was started around 1975 by Roy Lilwall of the Institute of Geological Sciences (later the British Geological Survey). Towards the end of the 1970s it was realized that seismic hazard in the United Kingdom needed to be considered in the context of the nuclear power program, and a large amount of effort was devoted to the historical investigation of British earthquakes over the next ten years. The result was a series of reports including notably Principia Mechanica Ltd. (1982), Soil Mechanics Ltd. (1982), Ambraseys and Melville (1983), Burton *et al.* (1984) and Musson (1994). The last of these is an attempt to synthesize all the results of the previous 15 y of research into a single consistent catalog.

4. Discussions

A concept recently introduced into historical seismology is that of the “roots” of an earthquake determination within a parametric catalog. The roots can be classified in terms of quality of supporting data, and a system has been proposed

(Stucchi and Camassi, 1997; Stucchi, *et al.*, 1999) grading the quality of any entry in a catalog of historical earthquakes. The best grading situation is that the entry is backed by a study containing intensity data points derived from primary historical sources, and the worst grading situation is that the entry is copied from another parametric earthquake catalog with the original data unknown. A large amount of historical research has been undertaken in the United Kingdom (aided, perhaps, by the fact that the total number of large earthquakes is not very great). Consequently, the situation for the UK catalog is that most earthquake determinations fall into the highest class, and almost all are based on data sets from primary historical data (Musson, 1996; Stucchi *et al.*, 1999). One can now say that our understanding of historical seismicity in Britain is in as good a shape as realistically can be achieved. A plot of earthquakes of magnitude $4.0 M_L$ or greater is shown in Figure 1. The full manuscript, of which this subchapter is an introduction, is given on the attached Handbook CD under directory \48.5Musson1.

1. Intensity and Intensity Scales

1.1 The Nature of Intensity

Intensity can be defined as a classification of the strength of shaking at any place during an earthquake, in terms of its observed effects. It can be compared to the Beaufort Scale of wind speed, and is not a physical parameter as such, although it is evidently related to physical parameters of strength of shaking. Also, one can think of it as a sort of shorthand for longer descriptions which may be common from one earthquake to the next. Thus, instead of writing that the earthquake was generally felt indoors at a certain place, and that dishes and cups rattled, one simply writes “intensity 4” (or whatever, according to the scale used) wherever this is the principal description. As a classification, it is essentially an integer quantity when assigned from observed data. Traditionally, Roman numerals have been used to represent intensity values to emphasise this point (it is hard to write “VII½”). Nowadays the use of Roman numerals is largely a matter of taste, and most seismologists find Arabic numerals easier to process by computer.

The word “macroseismic” is used to mean “pertaining to the perceptible effects of earthquakes” in distinction to “microseismic,” meaning “relating to instrumental observations of earthquakes.” The phrase “macroseismic data” can mean any assemblage of descriptive material on the effects of earthquakes, and need not necessarily include numerical intensities. The word “macroseismology” is applied to the study of earthquake effects.

Intensity scales normally consist of a series of descriptions of typical earthquake effects, each with an accompanying number, and arranged so that increasing numbers reflect increasing severity. This is not always the case; a few scales are arranged so that the lowest numbers express the strongest shaking. Also, other classificatory systems can be applied to macroseismic data, such as simple systems of

dividing reports into “no damage,” “damage,” and “heavy damage”.

It must be stressed at the outset that intensity is a classification of effects at a given place, and not a classification of an earthquake as a whole. Any earthquake is likely to produce different intensities at different places, generally decreasing with distance from the epicentre.

1.1.1 The Relation of Intensity to Sensors

Although intensity can be considered purely as a shorthand for a description of effects, it is also intended to be a measure of strength of shaking, and this introduces some important implications. An intensity scale typically consists of a number of a series of descriptions relating to each degree of the scale, and each description will consist of a number of component parts, usually referred to as diagnostics. Thus the description of intensity 5 in the 1956 Modified Mercalli Scale (MM56) reads “Felt outdoors; direction estimated. Sleepers wakened. Liquids disturbed, some spilled. Small unstable objects displaced or upset. Doors swing, close, open. Shutters, pictures move. Pendulum clocks stop, start, change rate” (Richter, 1958). There are therefore eight diagnostics for this degree of the scale, and the investigator will assign intensity 5 to a place if the data he has for that place more closely conform to these diagnostic descriptions than to any other ones in the scale.

Each diagnostic describes the effect of the ground vibration on some form of sensor. In the intensity degree described above, the sensors are: people outdoors, sleepers, liquids in containers, small unstable objects, doors, shutters or pictures, and pendulum clocks. In lower degrees of any scale, the most important sensors are people and domestic objects. In higher degrees, the emphasis moves to buildings as sensors, and higher degrees describe progressively more severe damage.

In the case of low intensity degrees, simple sensors like teacups can be considered to respond to the same degree of

shaking in roughly the same way. Thus, differences from place to place in the number of teacups that rattled or were spilt can be compared directly to differences in the earthquake shaking, and not to differences between the size or type of teacup. Since comparisons in the degree of shaking are what the seismologist wishes to make, items like teacups are good sensors for determining intensity. However, more diverse sensors require more explicit description. If one were to consider the diagnostic “objects fall over,” it makes a considerable difference if the “object” is a small, unstable ornament or a large heavy item like a TV set. It is therefore necessary to discriminate between objects that respond to shaking differently, in this case between small unstable objects and large, heavy, stable ones. In this case it is not difficult, and anyone can recognise that it takes more shaking to upset a large heavy object than it takes to knock over a small delicate one.

This becomes crucial when one comes to deal with damage to buildings. For buildings can be of very different strengths, and so when comparing damage from one locality to another it is vital to compare like with like. It was notable, for example, that the Latur earthquake of 1993, which caused many weak rubble masonry houses to collapse, produced very little damage to engineered structures in the same localities. One cannot therefore just use “damage to buildings” as a sensor; it is essential to consider damage to buildings of equivalent strength.

The earliest intensity scales tended to treat all buildings as equivalent, on the assumption that one would always be dealing with the “typical” construction of the country. Whether or not this was justified in the last century, it is not justified today. Later intensity scales used building construction type as an analogue of strength, which for the most part is a good practice. The most recent scale in general use, the European Macroseismic Scale (EMS), further acknowledges that condition and workmanship of a building can alter its strength considerably, and allows for downgrading or upgrading a building with respect to its vulnerability class (the classification of strength used in EMS-98) where the condition of the building requires it (Grünthal, 1998).

The finer the approach to assessing the details of the sensor, the harder it becomes for the seismologist to apply the scale. A key consideration here is robustness. An intensity scale must be a practical instrument, and the construction of the scale needs to steer a course between precision and ease of use. Any categorisation of building type that required the fieldworker to first take a degree in civil engineering before he or she could determine how to apply it to a particular observation, would be very undesirable. The degree of detail present in the EMS-98 is probably the maximum that can reasonably be employed at a practical level.

The hardest area of all concerns the use of effects on nature as sensors. Some outdoor observations are not problematical; for example, there is not so much variation in bushes that the shaking of bushes cannot be used as an intensity diagnostic.

But when it comes to effects on ground, the situation is rather different. It is well-known from numerous studies that the proclivity of slopes to failure (as rockfalls or landslides) is hugely dependent on a number of factors, especially those related to the prevailing hydrological conditions. These factors often vary considerably over short distances. As a result, the vulnerability of ground to failure is strongly variable, and has a large effect on the incidence of coseismic observations of slips, slides, fissuring, and so on. Just as it is not helpful to know that “an object fell” if one does not know if the object was a pencil or a typewriter, so also it is not helpful to know that a rockfall occurred if one does not know the strength of the slope beforehand. But whereas it is an easy matter to categorise objects such as pencils as small or large, it is, in practical terms, more or less impossible to usefully classify and recognise different strengths of slopes. As a result, observations of ground processes are of limited use in determining intensity. It has been objected that this restriction makes it practically impossible to derive intensity values for uninhabited areas. The answer to this is that, so far as meaningful values are concerned, it is indeed practically impossible to derive intensity values for uninhabited areas, and this is a fact of life, and it has to be conceded that nature is not arranged expressly for the convenience of seismologists.

This causes a further problem with some older intensity scales. It has been pointed out that in MM56, the description of intensities 11 and 12 depend on ground failure, and as ground failure is not entirely intensity-related, these two intensity values are essentially unusable (Bakun pers. comm., 1999). This is not a problem in EMS-98 where the highest intensity degrees depend on damage to buildings.

It may be the case that intensity values can saturate in some conditions. For instance, in areas where all structures are of very poor construction, such that all are totally destroyed at (say) intensity 9, it is then impossible to recognise intensity 10 in such an area. This is again, unavoidable.

The extent to which patterns of effects, corresponding to increasing degrees of shaking, can be recognised in working practice, determines the fineness of discrimination between different intensity levels that can be made. The general consensus of most major intensity scales on twelve roughly equivalent degrees, to cover the range from not felt to total destruction, is probably more than just conservatism or familiarity. Some authors (Shebalin, 1970; Dengler and Dewey, 1998) have argued for the practicality of discrimination of intermediate levels between the defined levels of a twelve degree scale, but any benefits from this are likely to be outweighed by the dangers of false precision in most cases. Some applications of intensity data do involve treating intensity degrees as if they were real numbers, however (see, for example, Section 3.2 below). It is also sometimes the practice in compiling computer files of intensity data to write an uncertain intensity value, which would normally be written 7–8 or VII–VIII (meaning either 7 or 8) as 7.5.

1.1.2 Assigning Intensity

Although detailed procedures may vary from case to case according to circumstances, the essential stages in assigning intensity can be described as follows.

1. The seismologist gathers all available information about the effects of the earthquake. This is discussed in more detail in Section 2.
2. The seismologist sorts the data by place. The division of places should be large enough for each place to contain a reasonable amount of data, and fine enough so as not to group together observations made in very different local conditions. Typically, data from a single village or small town will be treated together, whereas large towns and cities will be divided into suburbs or districts. One would not want to assign intensity to a single street; nor to a whole county.
3. The seismologist consults the intensity scale to determine which description of those for the various intensity degrees best fits the sum of the data for the particular place under consideration. The key concept here is coherence. It is not helpful to get lost in a pursuit of detail of individual diagnostics; the correct assignment is the one that best expresses the generality of the observations. Note that it is not desirable to try and assign intensities to each individual report and then combine them for a place; the data should be combined for the place first, and then one intensity value should be determined that best expresses the generality of the data.

It is not to be expected that all diagnostics will be satisfied by the data in all cases; for example, some may simply not be present. It is therefore advisable to adopt a flexible approach in seeking the best fit over the range of data available, rather than attempting to set up rigid formulas that depend on one or two key diagnostics only. It is important to look for an element of coherence in the data overall, rather than to rely on any one diagnostic as a yardstick. It is also necessary to be wary of giving too much weight to the occasional extreme observation, which might lead to an overestimation of the intensity at the place in question. For example, overreliance on damage as a diagnostic has in the past resulted in overestimation of intensities in cases where isolated, even anomalous, cases of damage have been used to base assessments on even though the mass of other data suggests a lower value.

Where the data consist of textual descriptions, the effects may be reported in terms far from the wording of the intensity scale. In such cases, it may be useful to consider whether the overall tenor of the description compares with the general character of a degree of the intensity scale.

Information that an effect definitely did not occur is often just as valuable as information that it did occur when determining intensity, and such data should not be neglected. However, to assume automatically that an effect did not occur,

just because it was not reported, is dangerous and invalid unless there are specific reasons why such an assumption can be justified. It should also be noted that no single effect is ever certain. This is important when attempting to infer a negative, rather than a positive conclusion. Just as it is possible to get an anomalous instance of damage even when the intensity is actually quite low, it is similarly possible for a vulnerable object to escape undisturbed even though the intensity was quite high.

Where data are simply insufficient to make a clear decision, it is necessary either to resort to the use of a range of values, for example, 7–8 (7 or 8) or >6 (7 or higher), or simply note that the earthquake was felt (usually denoted by the symbol F).

The use of automatic algorithms or expert systems to determine intensity values from a set of data is an interesting topic of current research, although it tends to be tied to a certain questionnaire format. Some examples can be found in Barbano and Salemi (1990) and Gasparini *et al.* (1992).

It is not good practice to try to “correct” intensity values for local soil conditions when assigning values. Soil conditions can be used to explain why certain intensity values are higher or lower than others in the vicinity. But as long as intensity is intended as a measure of what happened, the fact that a strong shaking was influenced in part by local conditions does not detract from the fact that the strong shaking did indeed occur.

In some cases it may be inadvisable to attempt to use certain data for assigning intensities. A particular case in point relates to observations from high buildings. It is well known that people in upper storeys are likely to observe stronger earthquake vibration than those in lower storeys. Various practices, such as reducing the assigned intensity by one degree for every so many floors, have been suggested, but never found general favour. Also, since very tall buildings may behave under earthquake loading in particular ways according to the frequency of the shaking and the design of the building, the increase of severity of shaking with elevation may be irregular. The recommended practice is to discount all reports from observers higher than the fifth floor when assigning intensity; although in practice the actual behaviour of individual buildings will vary considerably, depending especially on the slenderness of the building. In general, the user should be more concerned with effects observed under normal circumstances rather than in exceptional cases.

One special case is the situation where the only reports are from tall buildings, because the shaking was so weak that it was only perceptible on the upper floors of such structures. This sort of datum is typical of the lowest intensities perceptible.

Observations from special structures, such as lighthouses, radio towers, monumental buildings (such as cathedrals) etc., are difficult to use, as the responsiveness of such structures is impossible to categorise. Such data are best restricted to the status of complementing other information on which the intensity assessment depends. If such structures are the only source of information for a place, then it is important to

convey the uncertainty inherent in any assignment made from such data. A similar reservation applies to data from observers underground, which are not easily comparable with observations made at the surface.

It is not recommended to derive intensity values from instrumental measures of ground motion. An intensity value is intended as a description of what happened, not an inference from some recorded acceleration. The use of values derived in such a way is deceptive of the reader, who may believe that damage was recorded where in fact it was not. In addition, correlations between such parameters as peak ground acceleration and intensity are notoriously unreliable (Trifunac and Brady, 1975). Accelerations of 1–2*g* have been recorded on many occasions and these are usually not accompanied by especially high damage levels. If it is necessary (e.g., for disaster response purposes) to make predictions of what intensities might have been observed on the basis of instrumental recordings, then it should be made clear that the values are estimates of intensity and not observations.

1.2 The History of Intensity Scales

The use of intensity scales is historically important because no instrumentation is necessary to use them, and useful measurements of an earthquake can be made by an unequipped observer. The earliest recognisable use of intensity was by Egen in 1828, although simple quantifications of damage had been made in the previous century by Schiantarelli in 1783 (Sarconi, 1784), and some earlier Italian examples are said to exist. However, it was only in the last quarter of the 19th century that the use of intensity became widespread; the first scale to be used internationally was the ten-degree Rossi-Forel Scale of 1883. The early history of intensity scales can be found in Davison (1900, 1921, 1933); a later study was made by Medvedev (1961).

The scale of Sieberg (1912, 1923) became the foundation of all modern twelve-degree scales. A later version of it, known as the Mercalli–Cancani–Sieberg Scale, or MCS Scale (Sieberg, 1932), is still in use in Southern Europe. The 1923 version was translated into English by Wood and Neumann (1931) and became the inappropriately named Modified Mercalli Scale (MM Scale). This was completely overhauled in 1956 by Richter (1958) who refrained from adding his name to the new version in case of further confusion with “Richter Scale” magnitudes. Richter’s version became instead the “Modified Mercalli Scale of 1956” (MM56) despite the fact that the link to Mercalli was now extremely remote. Local modifications of Richter’s MM56 scale have been used in Australia and New Zealand among other places. More recent attempts to modernise the MM scale further, e.g., that of Brazee (1978), have not caught on.

In fact, the 1931 version of the MM scale is still officially in use despite the fact that it is nearly 70 y old and has been effectively obsolete for some time. Dengler and Dewey (1998)

note that in fact, routine use of the MM31 scale differs substantially from a literal reading of the 1931 text, so as to incorporate the result of the succeeding six decades of experience of assigning intensities to US earthquakes. This is good from the point of view of the quality of intensity data sets that are produced, but it does mean that procedures are not so transparent as they should be, and the data sets cannot easily be deconstructed or reconstructed by other workers who lack access to the extra rules and conventions being applied.

In 1964 the first version of the MSK Scale was published by Medvedev, Sponheuer and Karnik (Sponheuer and Karnik, 1964). This new scale was based on MCS, MM56 and previous work by Medvedev in Russia (the GEOFIAN scale), and greatly developed the quantitative aspect to make the scale more powerful. This scale became widely used in Europe, and received minor modifications in the mid 1970s and in 1981 (Ad hoc Panel, 1981). In 1988 the European Seismological Commission agreed to initiate a thorough revision of the MSK Scale. The result of this work (undertaken by a large international Working Group under the chairmanship of Gottfried Grünthal, Potsdam) was published in draft form in 1993, with the final version released (after a period of testing and revision) in 1998 (Grünthal, 1998). Although this new scale is more or less compatible with the old MSK Scale, the organisation of it is so different that it was renamed the European Macroseismic Scale (EMS). Since its publication it has been widely adopted inside and also outside Europe. Despite its name, the EMS is easily adaptable for use with the built environment of any place in the world.

As with the MM scale, it was recognised that procedures and conventions were being applied to the use of the MSK scale in best practice, which were often not written down or defined. One of the objectives of the EMS Working Group was to encapsulate these formally into the scale. This was done by incorporating extensive guidelines for use into the text of the scale. In this way, the operation of the scale becomes more transparent, and therefore discrepancies in practice between different users over time, or between region and region, should be reduced.

The one important intensity scale that does *not* have twelve degrees is the seven-degree Japanese Meteorological Agency Scale (JMA Scale). This is based on the work of Omori, and is the scale generally used in Japan and Taiwan. A recent revision (JMA, 1996) has increased the number of degrees in the JMA scale to ten, with intensities 5 and 6 now being subdivided into “lower 5,” “upper 5,” “lower 6,” and “upper 6.” The historically important Rossi-Forel Scale is no longer much in use, except in the Philippines (Dewey, 2000 pers. comm.).

To some extent the middle years of the 20th century saw a decline in interest in macroseismic investigation, as progress was made in improving the power of instrumental monitoring. When earthquakes could be located accurately by instrumental means, and their magnitude and depth similarly determined, it might well have seemed redundant to pay attention to

earthquake intensity. However, since the middle 1970s there has been a strong revival of interest in the subject since macroseismics are essential for the revision of historical seismicity and therefore of great importance in seismic hazard assessments. Macroseismic studies of modern earthquakes are vital for (1) calibrating studies of historical earthquakes; (2) studying local attenuation, and (3) investigations of vulnerability, seismic hazard and seismic risk.

1.3 Intensity and Iseismal Maps

The presentation of intensity data is usually done in the form of a map. As well as plotting intensity points, it is usually useful to be able to draw contour lines of equal intensity, called isoseismals. An isoseismal can be defined as a line bounding the area within which the intensity is predominantly equal to, or greater than, a given value. Drawing isoseismal lines is therefore a process of contouring the strength of shaking of an earthquake over the area in which it was felt.

No precise instructions can be given for drawing isoseismals as no definitive method has ever been agreed. Some workers adopt a practice of overlaying a grid on the data and taking the modal value in each grid square prior to contouring, others prefer to work directly on the plotted intensity values. Workers have differing preferences for the amount of smoothing, extrapolation, etc., that is to be employed. Thus, at present, the drawing of isoseismals is to some degree subjective.

However, some guidelines can be given. The degree of smoothing employed should reflect the purposes to which the resulting map will be put. If the map is intended for local studies, i.e., to point up areas where seismic hazard may be enhanced owing to local soil conditions, then smoothing will be applied to a lesser extent, and isoseismals will be relatively convoluted. If the map is intended for other purposes (calculation of earthquake parameters, attenuation studies, tectonic studies, etc.) then the curves will normally be smoothed so that only major re-entrants and outliers are shown. The latter case is more common, and can be regarded as the default.

Excessive detail is never justified, given the limits of resolution of the data. As a general rule, re-entrants and outliers should not be drawn unless suggested by a grouping of at least three data points. If isoseismals have to be interpolated or extrapolated across areas of water, or areas without data points, these sections of the lines should be shown as dashed. In cases where, for example, an epicentre is offshore, and only (say) a 120° arc of each isoseismal would fall onshore, it is not correct to project the whole of the remaining 240° of each isoseismal on a map, even as a dotted line. Only the onshore section should be drawn, with each line tailing off with a short dotted section offshore if desired. Plotting isoseismals that are completely offshore and merely projections of an intensity attenuation curve should not be done. For onshore earthquakes with few data, it is not good practice to attempt to draw isoseismals conjectured from one or two points only; at least

three mutually supporting data points for one intensity value should exist before one attempts to draw even a partial isoseismal for that value.

The aim of producing isoseismals is a little different from other contouring exercises. Each data point does not necessarily carry the same weight. This is because the purpose of an isoseismal is to delimit areas where the intensity generally exceeded a certain value. Residuals within this area are to be expected, either through soil conditions, sampling effects, or some other cause. These residuals are generally ignored in drawing isoseismals, as it is usually more important to display the general trend of the data under average ground conditions than to point out deviations from this.

As a result, computer contouring programs usually do not give good results with macroseismic data. Whereas the human eye readily spots the residuals to be ignored, computer algorithms cannot do this with the same ease.

It is also recommended that seismologists should preserve and publish tables of intensity data (place, geographical coordinates, intensity) whenever possible. The practice of publishing isoseismal maps without the underlying data either plotted or tabulated, results in the user being unable to determine how much judgement has been exercised in plotting the isoseismal lines.

1.4 Intensity Attenuation

Intensity attenuation, the rate of decay of shaking with distance from the epicentre, can be expressed in two ways. Firstly, there is the drop in intensity with respect to the epicentral intensity. This is shown by the Kövesligethy (1906) formula discussed in Section 3.4; this form of intensity attenuation and depth determination from intensity are closely linked. One can also express intensity attenuation as a function of magnitude and distance. Such formulas usually have the functional form

$$I = a + bM + c \log R + R + dR \quad (1)$$

where R is hypocentral (slant) distance, and a , b , c and d are constants. (The fourth term is sometimes dropped, especially in intraplate areas.) Since most earthquake catalogues include magnitude as a parameter, this form of intensity attenuation is extremely useful in seismic hazard studies. Intensity is sometimes a good parameter to use for expressing seismic hazard, since it relates directly to damage. It yields hazard values which are probably more relevant to planners and insurers than physical ground motion parameters (discussed further in Section 4.1).

Some typical values are:

Interplate (New Zealand):

$$I = 2.18 + 1.41 M_S - 1.18 \ln R - 0.0044 R \quad (2)$$

Intraplate (SE Australia):

$$I = 4.00 + 1.64 M_S - 1.70 \ln R \quad (3)$$

the sources for these equations being Dowrick (1992) and Gaull *et al.* (1990).

It should be remembered when calculating intensity attenuation, that such equations should represent intensity given normal soil conditions, and therefore high residual data points (resulting from local ground conditions) in a set of macroseismic data should be discounted for this purpose. This is so that site correction factors can be applied when the attenuation equation is being used in a predictive sense, without danger of circularities arising.

2. Macroseismic Surveys

After an earthquake is felt in a region, there are several possibilities as to how to collect the data. The final choice depends on many factors, such as:

1. how strong the earthquake was, and, therefore, how important the data are;
2. whether it was a single shock or a part of a long sequence;
3. if there is already an existing network of earthquake observers in the region, and whether the network is dense enough;
4. the financial situation of the institution that collects the data, etc.

These points will now be considered in more detail.

In many countries there is a practice that macroseismic data are not collected for every single felt earthquake, but a certain threshold is set. It might be that the data are collected only if the magnitude or intensity of the earthquake was larger than some threshold value, or even only in cases that the earthquake has caused some damage. For example, in the United Kingdom surveys are normally done for all earthquakes with onshore epicentres and magnitudes greater than $3 M_L$, and for offshore events with a significant felt area. In Italy the magnitude threshold is also set to 3, but the questionnaires are sent even for weaker events if the maximum intensity exceeded 5 MCS (Mercalli–Cancani–Sieberg scale). On the other hand, some smaller countries, as well as countries with low seismicity, such as Hungary, Austria, Slovenia etc., can afford to collect data actively for almost every earthquake felt on their territory. In areas where earthquakes are rare, the data for even a weak earthquake might be much more valuable and useful for the study of seismicity than the data for a stronger event in the region where the average activity is high.

After a strong main shock there is often long and recurrent aftershock activity. In such cases, people feel so many earthquakes that after some time they start to forget what they felt during any particular event. Also, in the aftershock sequence there tend to be several, or even many, events of approximately the same maximum intensity, as well as magnitude and co-ordinates. Getting the macroseismic data for all the

aftershocks is impossible; therefore in practice seismologists often have to make decisions and collect the data only for some events.

Several seismological institutions have organised permanent networks of voluntary observers in the field. In the case of an earthquake, the questionnaire forms are distributed to them by mail, or they already have some at home, office etc. For small earthquakes such a method is usually enough. However, for a damaging earthquake even the best network of observers is not sufficient, so additional field work is necessary in order to get as many data as possible from the epicentral area.

Although it might sound trivial, the method that is going to be used in collecting the macroseismic data depends heavily on the financial situation of the institution. Regardless of the scientific reasons, it is unfortunately frequent that in everyday practice data are not collected even for important events due to a momentary lack of funds for stamps, films, daily allowances or other material necessary for field trips.

2.1 Questionnaire Design and Distribution

2.1.1 Questionnaire Design

Macroseismic questionnaires are forms consisting of questions about the earthquake; some forms have built-in already the selection of possible answers, so the observer can choose among them (multiple choice questions); others give the observer the possibility to express his impressions in his own words (free-form questions). The point of having a questionnaire is primarily to have all the data in more or less the same format, which means that all the questions are asked of the whole population of observers in precisely the same way. It makes the collected data comparable within the data set for the same earthquake, as well as between different events (for which the same type of form was used).

There are several types of questionnaire forms being used, depending mostly on the target population and the type of the data that one wishes to collect.

The commonest case is a general form, consisting of a set of questions that follow the chosen macroseismic scale. In many cases the questionnaire includes also some additional questions, that are not strictly included in the scale, but might be useful in having a more complete description of the earthquake effects.

Some institutions have two versions of the same form, with and without the questions on damage, for strong and weak earthquakes, respectively. The point of having the shorter version of the questionnaire is not to burden the observers with too many questions in case of weak events. Since one usually relies on the goodwill of observers to fill in a questionnaire at all, it makes sense not to make the questionnaire unnecessarily long, difficult, or otherwise discouraging.

Generally the questionnaire form will be too complicated for children in primary schools, although they can be a very valuable source of data, especially in rural areas, where

children from a relatively large area can be in the same class. Therefore a special form can be arranged for them; instead of the printed form, the questions are read to them one after the other, and all the necessary explanation is given.

After a damaging earthquake, there are a lot of data to be collected in the field; special forms can be constructed in order to make this procedure easier. The use of the EMS scale requires the seismologists to collect detailed data on type of objects and damage. The experience from the recent damaging earthquakes in Europe (1997 Central Italy, 1998 northwest Slovenia) has produced some preliminary forms for describing the damage on single objects, as well as for the whole settlement. An example of the questionnaire form for the assessment of damage on single buildings was proposed by Tertulliani *et al.* (1996/99) and is attached as Appendix 1 on the attached Handbook CD, under directory \49Musson2.

2.1.2 Questionnaire Distribution

There are several ways of distributing questionnaires that are being routinely used by seismologists: (1) by mail, (2) by press, (3) by e-mail, (4) by phone, (5) by making a request through the radio/TV, and (6) by direct distribution.

The most commonly used method for the distribution of questionnaires is surely by mail. In some countries it can be done free of postal charges, whereas others are not so lucky. Generally the method is the following: after an earthquake, the addresses of the observers from some database are printed onto the questionnaires and sent to them; the answers are then sent back using the spare envelope that was included or folding the card according to the instructions. The address database can be one constructed especially for use in macroseismology, or a more general one (phone book etc.) can be used. The ideal procedure is to send questionnaires to a completely random sample of respondents in the affected area, the sample being derived from some source such as electoral rolls. The advantage of this is that accurate statistical conclusions can be drawn about effects on the whole population from the analysis of the sample; the methodology is well known in the social sciences. The drawback is that setting up an appropriate random sample can be time-consuming, and such a task may be difficult to manage in the immediate wake of an earthquake. If one waits too long before distributing questionnaires, the chances are that many people will already have forgotten the details of their experience.

Experience shows that a very good percentage of answers can be achieved, especially with a selected database of respondents, if the database is kept promptly updated. It takes a relatively short time to print and pack the mail, but in cases where the postage has to be paid and in cases of either a large earthquake or a very busy year it might become quite costly. On the other hand, it gives homogeneous and comparable data, and the preparation of the intensity list is fast, because the coordinates of the places are already prepared.

One way to encourage response is to combine the questionnaire survey with some sort of raffle; the sender of one randomly drawn questionnaire wins a small prize, such as a box of chocolates. This gives the respondents an additional motivation for sending in a reply, which might be useful particularly in making sure negative data are adequately represented.

Some countries, such as the United Kingdom, have very good experience with having questionnaires printed in some newspapers (Musson, 1992); in others, such as Italy, the idea seems not to work so well (Riggio and Slejko, 1989). After an earthquake is felt in the region, the questionnaire is printed in one or more local or regional newspapers, and the readers are encouraged to fill in the answers and send them back. The method does not take much time to launch (the questionnaire form is usually already prepared and ready to be used), but it can be quite time-consuming afterwards, especially in the case of large numbers of answers, that need to be sorted and the coordinates for every single place defined. Another disadvantage of this method is that the questionnaire sample is not truly random and may be biased toward those people who felt the earthquake.

Lately there is some experience with collecting macroseismic data using electronic media. Several institutions have their questionnaire forms on their Internet home pages, and they receive some answers by e-mail. It is possible to foresee that this method may become more and more used in future. There is particular interest in this method in the United States, where there is probably a higher proportion of people on-line than in most other countries.

Collecting the data by telephone cannot be treated as a regular questionnaire distribution, but more like polling. Of all the methods mentioned here, it is the most time-consuming and possibly the most expensive as well. However, if a seismologist can not send questionnaires or print one in the newspapers, or go into the field, the telephone is the only available method to collect the data. One should be very careful when asking questions, in order not to suggest the expected answer to the person who is giving the data. In some countries, e.g., USA, this method of collecting the data would not be possible for governmental institutions owing to legal restrictions. Telephone data collection is perhaps best suited for establishing whether a small event at the threshold of perceptibility was felt at all, especially in rural locations, where a few farms and perhaps a hotel are the only places that need be consulted.

After each strong earthquake, there is usually a lot of interest from the media about the details. This gives the seismologist an opportunity to speak (on the radio or TV) directly to the population, explaining briefly what data are of particular interest and asking people to write down their descriptions of the earthquake and send them to the institution that collects the data. An experience from Slovenia showed an unexpectedly good response of listeners to the national radio

that broadcast the request several times (for an earthquake of $4.1 M_L$ and maximum intensity 5 MSK in 1990 approximately 160 letters were received).

Direct distribution of questionnaires after the earthquake can be used if the problem of returning the questionnaires to the institution in charge is solved. Then a pile of questionnaires could be left, for example, in post offices with the sign "Please take one" and clear instructions what to do afterwards. If the questionnaires are free of postal charges, then they can be simply posted back. If not, a box for collecting them or an alternative method should be arranged.

2.2 Field Surveys

Field survey is an obligatory tool that complements the above-mentioned methods in the case of a damaging earthquake (producing intensities of 6 EMS or higher). It can be used also for weaker events, in cases where the expected number and spatial distribution of returned questionnaires would not be enough to make a clear picture of earthquake effects in some part of the felt area.

Field surveys require some necessary equipment, such as good and detailed road maps of the area to be surveyed, questionnaires, notebooks and pencils, copies of the macroseismic scale, camera, and of course sturdy shoes, rainproof clothes, and sunglasses. A portable tape-recorder and a laptop computer might also come handy.

Field survey is usually best done by car, although some other methods of transport can be used in cases where there are several teams working on the same earthquake. The ideal team consists of a seismologist and a driver. In extreme cases, e.g., where the road network is impassable due to bridge damage, a helicopter may be required, preferably in collaboration with civil defence teams, the military, etc.

While interviewing people, one can use several methods; the answers can be filled directly into a questionnaire form, or written in free format in a notebook. The answers can be recorded on tape directly (if the person who is giving the data agrees, which is not often in rural areas) or the seismologist can repeat a summary of what was said into the voice recorder after finishing the conversation. In any case one must be very careful to label all the data carefully, in order to avoid any confusion.

Collecting the data in a small settlement is one as follows: Usually soon after the car is parked people come around and start telling what happened. Their answers, as well as their addresses are written in the notebook or recorded on the tape. If the earthquake caused some damage, this is the fastest way to learn where to find it. If possible, it is very desirable to take photographs of damage and keep records of it. Then a short survey of the settlement should be done, taking notes on the total number of buildings of each category (if EMS is used) and the number of damaged ones, as explained in the scale.

If the locality is still populated after the earthquake, it is usually very useful to visit briefly some points where people

come together (shop, post office, parish office, hairdresser, local pub etc.). A visit to a school in rural area can give a lot of data in relatively short time, because in the same class one can find children living in many different villages or isolated farms.

If the intensity in a locality was high and the houses are badly damaged, the inhabitants will usually be living in improvised shelters and not in the village. In that case the entrance to the settlement may be closed and the field team should contact the local authorities in order to obtain the necessary documents to visit the damaged area. They (civil defence, firemen, police etc.) are also a very useful source of data on the damage and usually can point out some interesting cases. Some identification (such as a badge with the name of the member of the team as well as the name of the institution one works for, or at least a letter that certifies that) is very useful to have, as well as a helmet and a battery lamp.

In a case of a large settlement (small or big town) it is impossible to make a complete detailed survey and count every house. One should then contact the local authorities and see which would be the areas of particular interest. If the locality is still populated, the fastest method to collect data is a visit to schools, preferably for older children. The whole address including street and number written on their answers is necessary in order to be able to divide the town into smaller fractions (quarters, wards) when doing more detailed intensity studies. However, where heavily damaged areas have been evacuated and cordoned off, damage data on a house-to-house basis may be ultimately available through co-operation with the civil defence authorities.

It is necessary to stress that a good macroseismic survey for a damaging earthquake can not be done without co-operation with civil engineers. It is especially important to establish such co-operation in cases when the damaged area is large, although it is highly recommended to include a civil engineer in field teams every time there is damage, however slight it might be. Seismologists generally lack training and experience in civil engineering, and identifying the building vulnerability class may be difficult, especially in cases of engineered structures and buildings that have been modified to include some sort of earthquake resistance. Examples from recent earthquakes have shown that without close co-operation with civil engineers, the accurate assessment of damage, as well as intensity, would be difficult, if not impossible (Cecić *et al.*, 1999).

2.3 Review of Some Existing Practices

2.3.1 Italy

In Italy the practice of collecting and evaluating the macroseismic data has been a long and fruitful one. Istituto Nazionale di Geofisica (ING, National Institute for Geophysics) in Rome is at present the largest institution in Italy that collects

macroseismic data. However, it is soon to be merged with some other important Italian seismological institutions into the new Istituto Nazionale di Geofisica e Vulcanologia (INGV, National Institute for Geophysics and Vulcanology).

Italy is a country with relatively high seismicity, and every year there are many earthquakes felt on its territory. Therefore at ING, intensity data are not collected for every earthquake, but only for those that exceed 3.0 in magnitude. Even so, the questionnaires are still sent for weaker events if the maximum intensity exceeded 5 MCS. The questionnaires are based on the MCS scale and consist of 79 questions, that cover the effects between 2 and 10 MCS. The questionnaire is shown in Appendix 2 on the attached Handbook CD, under directory \49Musson2 (or visit http://ing712.ingrm.it/data_www/Macros/questing.html). Field surveys are made after damaging events.

ING maintains a network of correspondents that report on earthquake effects and fill in the questionnaires (Tertulliani and Maramai, 1992). The network involves some public bodies, such as municipal authorities, the Forest Corps, and the Carabinieri Police Corps, i.e., approximately 13 000 correspondents. This configuration has been operative since 1987.

When evaluating the intensity data an algorithm is used, in order to make the evaluations more objective (Gasparini *et al.*, 1992). The intensity evaluations and the intensity maps are regularly published in quarterly Macroseismic Bulletins. An example of the output for an earthquake is shown in Appendix 3 on the attached Handbook CD, under directory \49Musson2. ING exchanges macroseismic data with neighbouring countries on a regular basis.

2.3.2 Austria

Austria is a country with relatively low seismicity. The history of collecting macroseismic data on the territory of present-day Austria begins at the end of the 19th century, when an "Earthquake Commission" was established in order to compile the earthquake catalogue for the Austro-Hungarian Monarchy, and to establish a network of both seismograph stations and permanent macroseismic observers (Fiegele, 1989). Since then the macroseismic data have been collected and evaluated on a regular basis. Today the institution in charge is Zentralanstalt für Meteorologie und Geodynamik (ZAMG, Central Institute for Meteorology and Geophysics) in Vienna.

In 1947 an arrangement was made with the Ministry of the Interior providing that, in the case of an earthquake, each police station from the region where it was felt should send a report to ZAMG. Today police stations are still the principal contributors, apart from those people who send their reports spontaneously. In the case of a stronger and larger earthquake, additional questionnaires are sent to schools, municipal offices, post offices etc., and a short announcement with the request for reports is given to Austrian News Agency, the radio, and the TV station.

The reports are interpreted according to the EMS scale. The isoseismal lines are drawn and the focal depth and the macroseismic magnitude of the earthquake are calculated. Finally, the maps and a short description are printed and mailed to everybody who contributed to it (Appendix 4 on the attached Handbook CD, under directory \49Musson2). Austria exchanges macroseismic data with neighbouring countries on a regular basis.

2.4 Macroseismic Studies of Historical Earthquakes

Macro seismology is among the rare branches of seismology that can be applied to the research of events that happened before seismological instruments were invented, and for regions where no such instruments were ever installed. The necessary condition is that the region was populated and that the inhabitants left some record about the earthquakes that happened in their time. Moreover, macroseismic methods are the only means by which one can produce earthquake catalogues for the time before the 20th century, and are very important in studies of hazard (see Section 4.1).

When dealing with preinstrumental earthquakes, the seismologist often encounters several problems that can not be solved without the close co-operation of a trained historian. Institutes in some countries, for example Austria and Italy make it a practice to employ professional historians, who study the historical material (chronicles, newspapers, reports, letters, etc.) and prepare it for seismological interpretation. Many studies of historical earthquakes that were compiled in the earlier part of the 20th century (or in the 19th century) made many errors because of a lack of understanding of the precepts of historical studies on the part of the seismologists who conducted them. This subject is discussed at greater length in the sections on historical earthquakes.

3. Deriving Macroseismic Parameters

There are two basic approaches to deriving most earthquake parameters from macroseismic data. The first is to draw isoseismals and use the enclosed areas, or the average radii. The second is to base the calculations on the intensity data points themselves, without drawing isoseismals. The advantage of the second approach is that any subjectivity in the isoseismal drawing is entirely circumvented. The disadvantage is that the results may be biased by heterogeneity in the distribution of intensity points as a result of variations in population distribution.

3.1 Epicentre and Barycentre

The epicentre of an earthquake as derived from macroseismic data is something, which, in the past, has been approached in

different ways (Cčić *et al.*, 1996). The following usage is proposed for the future:

- **Macro seismic epicentre:** The best estimate made of the position of the epicentre (i.e., the point on the Earth's surface above the focus of the earthquake) without using instrumental data. This may be derived from any or all of the following as circumstances dictate: position of highest intensities; shape of isoseismals; location of reports of foreshocks or aftershocks; calculations based on distribution of intensity points; local geological knowledge; analogical comparisons with other earthquakes, and so on. This is a rather judgmental process with some subjectivity, and does not lend itself to simple guidelines that can be applied uniformly in all cases.
- **Barycentre:** The point on the Earth's surface from which the macro seismic field appears to radiate. This is often the centre of the highest isoseismal or the weighted centre of the two highest isoseismals. Other methods have also been proposed, such as the point from which application of an attenuation equation to the whole data set produces the lowest residuals (e.g., Peruzza, 1992). Such methods have the advantage of not requiring the drawing of isoseismals at all. However, to determine the barycentre by calculating, say, the geometric mean of the data points equal to the highest and second highest intensity value, would run the risk of the resulting location being pulled toward the area with the highest number of settlements. This is a good illustration of the value of drawing isoseismals. Other synonymous terms proposed are "intensity centre" (Bakun and Wentworth, 1997) and "macrocentre" (Cčić pers. comm., 1994).

The macro seismic epicentre and barycentre are often the same, but need not be. As an example, in the case of the 1989 Loma Prieta earthquake the apparent point of origin of the macro seismic field was, for various reasons, to the north of the actual instrumental epicentre. If one were to attempt to locate a similar event from macro seismic data alone (for example, a historical Californian earthquake) one might be inclined to compensate for this effect by choosing epicentral co-ordinates to the south of the highest isoseismal. This would not affect the location of the barycentre.

Both these concepts have their uses. For any study of the tectonics of an area, the macro seismic epicentre is more useful. For studies of seismic hazard, especially those using a technique like extreme value statistics, the barycentre may give a better indication of the hazard potential of an earthquake.

3.2 Epicentral Intensity (I_o)

Epicentral intensity, usually abbreviated I_o , is a parameter that is commonly used in earthquake catalogues but rarely defined,

and it is clear that different usage exists in practice (Cčić *et al.*, 1996). The meaning of the term is clearly the intensity at the epicentre of the earthquake, but since it is likely that there will not be observations exactly at the epicentre itself, some way of deriving this value is necessary. The two main techniques that have been used in the past are:

1. Extrapolation from the nearest observed data to the epicentre without changing the value, or use of the value of the highest isoseismal. Thus if there are a few data points of intensity 9 near the epicentre, the I_o value is also 9. If the epicentre is significantly offshore, I_o cannot be determined.
2. Calculating a fractional intensity at the epicentre from the attenuation over the macro seismic field, using a formula such as that by Kövesligethy (1906) or Blake (1941). In this case, because this is not an observed value (and not a "true" intensity) it may be expressed as a decimal fraction without contravening the rule that intensity values are integers. This value can be determined for earthquakes with sufficient data to draw at least two (preferably three) isoseismals. This is only possible if one is using the concept of the barycentre (see Section 3.1), since the true epicentre may not be central to the macro seismic field. The term "barycentral intensity" might be preferable.

It is recommended that these two methods be discriminated between by the notation used. Thus an integer number (9 or IX) indicates method (1) and a decimal number (9.0 or 9.3) indicates method (2). It is recommended that one should not add arbitrary values to the maximum observed intensity when deriving an I_o value; the arbitrary amount is too subjective. As well as epicentral intensity, a useful parameter is maximum intensity, abbreviated I_{max} . This is simply the highest observed intensity value anywhere in the macro seismic field. For onshore earthquakes, I_o and I_{max} may be equal. For offshore earthquakes it is often not possible to estimate I_o (never if method 1 is used), but I_{max} can be given.

3.3 Magnitude

The use of macro seismic data can give surprisingly robust measures of earthquake magnitude. This is an extremely important part of macro seismic studies, as in this way earthquake catalogues can be extended into historical times with consistent magnitude values. Such extended earthquake catalogues are of great benefit to seismic hazard studies. Early studies attempted to correlate epicentral intensity with magnitude; however, epicentral intensity can be strongly affected by focal depth, so such correlations may perform poorly unless either (1) depths are known and taken into consideration, or (2) one is working in an area where seismogenic depth is narrowly constrained.

The total felt area (A) of an earthquake, or the area enclosed by one of the outer isoseismals (usually 3 or 4), is a much better indicator of magnitude, being not much affected by depth except in the case of truly deep earthquakes. For earthquakes below a threshold magnitude (about $5.5 M_w$) magnitude and log felt area scale more or less linearly, and so equations of the form

$$M = a \log A + b \quad (4)$$

can be established regionally by examination of data for earthquakes for which macroseismic data and instrumental magnitude are both available. For larger earthquakes, differences in spectral content may affect the way in which earthquake vibration is perceived, and a different scaling appears to apply. In Frankel (1994) the form

$$M = n \log(A/\pi) + 2m/(2.3\sqrt{\pi})\sqrt{A} + a \quad (5)$$

is used to represent the full magnitude range, where n is the exponent of geometrical spreading and

$$m = (\pi f)/(Q\beta) \quad (6)$$

where f is the predominant frequency of earthquake motion at the limit of the felt area (probably 2–4 Hz), Q is shear wave attenuation and β is shear wave velocity (3.5 km sec^{-1}). Using this functional form and comparing worldwide intraplate earthquakes with interplate earthquakes from one region (California), Frankel found the difference in magnitude for the same felt area to be on average 1.1 units greater for California.

Other forms that have been proposed include

$$M = aI_o + b \ln r + c \quad (7)$$

where r is the radius, rather than the area, of the total macroseismic field, and

$$M = aI_o + \sum b_i \ln r_i + c \quad (8)$$

in which all isoseismals (values for each i) are used as well as the epicentral intensity (see Albarello *et al.*, 1995).

The method of Bakun and Wentworth (1997) is of particular interest in making a joint determination of epicentre and magnitude by drawing contours of goodness-of-fit to the intensity data set of possible epicentres and magnitudes. This method is especially suited in cases where the intensity data set is sparse.

In the above equations, M has been used for generic magnitude; for any particular magnitude equation it is important to specify what magnitude type the derived values are compatible with (M_s , M_L , M_w , etc.). It is also useful to determine the standard error, which will give a measure of the uncertainty attached to estimated magnitude values.

3.4 Depth

The estimation of focal depth from macroseismic data was first developed by Radó Kövesligethy. His first paper on the subject presented the formula

$$I - I_o = 3 \log \sin e - 3\alpha(r/R)(1 - \sin e) \quad (9)$$

where $\sin e = h/r$ and R is the radius of the Earth (Kövesligethy, 1906). Equation (9) was subsequently rewritten and modified slightly by Jánosi (1907), to reach the better-known formula

$$I_o - I_i = 3 \log(r/h) + 3\alpha \log e(r - h) \quad (10)$$

where r is the radius of the isoseismal of intensity I_i , h is depth, and α is a constant representing anelastic attenuation. In this form the equation has been much used (e.g., Burton *et al.*, 1985). The constant value of 3 represents an equivalence value between the degrees of the intensity scale and ground motion amplitudes. Some workers accept it, others prefer to find their own values by fitting to data (Levret *et al.*, 1996). The attenuation parameter α should usually be determined regionally by group optimisation on an appropriate data set rather than for individual earthquakes, since one assumes that this value, a property of the crust, does not alter from earthquake to earthquake.

This technique is also associated with the name of Blake (1941), whose contribution was essentially a reduction and simplification of Eq. (10); Blake's version is still used by some workers today, but Kövesligethy's original equation (in Jánosi's version) is more commonly encountered. Kövesligethy's equation became more widely known, in the form of Eq. (10), through a paper by Sponheuer (1960).

I_o here is properly the barycentral intensity, which has to be solved for in addition to solving for h . This is usually done graphically; one can fit the isoseismal data to all possible values of h and I_o and find a minimum error value consistent with the observed maximum intensity (e.g., Musson, 1996).

A test made by Musson (1993) in comparing macroseismic depths and instrumental depths for modern British earthquakes found that the mean discrepancy between the two depth values was 1.6 km. This represents working with the most favourable sort of data for the method, i.e., from shallow (5–25 km) intraplate events with very small sources and good macroseismic data.

3.5 Source Parameters

It is possible to find on occasional papers that present focal mechanisms for preinstrumental earthquakes. These are commonly the result of a chain of reasoning which can be summarised as: "this earthquake occurred in such-and-such a place, therefore it must have been produced by such-and-such a fault, therefore it must have had a focal mechanism consistent with

the type of faulting on this fault.” Although the result of this reasoning may sometimes be correct, particularly in cases where the causative fault is obvious from surface rupture, the process cannot be considered as a determination of earthquake parameters so much as educated guesswork.

The first attempt to use a processing of macroseismic data to characterise actual fault parameters can be found in the work of Charles Davison, starting around 1890 in the United Kingdom, which is remarkable since this actually predates the use of instrumental data for determining focal parameters. Davison believed that he could use detailed descriptions of perceived ground motion from human observers to derive analytically the strike and dip of the rupturing fault (Davison, 1891). However, he was unaware of the extent to which perceived direction of motion is distorted by building response (most of his observers being indoors), and his method is overly ambitious and of no practical value.

Modern approaches to the determination of source parameters usually depend on the assumption that the ellipticity of isoseismals is a certain indicator of fault azimuth. The work of Shebalin (1973) seems to be the first attempt to follow this line of approach. Although in some cases it is obviously true that elliptical isoseismals are aligned along the fault axis, there is also the possibility that this simple pattern is distorted by radiation patterns and local effects (especially for smaller events). Subsequent studies along these lines are summarised by Gasperini *et al.* (1999), who points out the absence of adequate testing of the various methods against calibrated modern data.

A recent method, proposed by Gasperini *et al.* (1999), is as follows: (1) locate the epicentre of the earthquake from the highest intensity observations; (2) assess the seismic moment from an algorithm involving the median distance for the observations of each intensity value; (3) infer the source dimensions from the moment; (4) assess the fault azimuth, essentially from the direction of maximum elongation of the highest isoseismals. The authors have tested the method against some recent large Italian earthquakes ($5.5 M_s$ is considered to be the minimum size of earthquake for which the method is reliable) with satisfactory results. It will be an interesting exercise in the future to test this method in other areas.

A study by Parsons *et al.* (2000) applied the method of Bakun and Wentworth (1997) to intensity data for six large earthquakes in the Marmara Sea region of Turkey, and attempted to identify probable causative fault ruptures by comparing contours of epicentre and magnitude goodness-of-fit to the intensity data set with compatible fault segments.

4. Applications of Macroseismology

4.1 Seismic Hazard

Since the late 1970s it has been realised that macroseismic methods are essential for most seismic hazard studies. The

corresponding increase of interest in seismic hazard necessitated by expanding nuclear energy programmes throughout the world, has ensured a large resurgence of interest in macroseismology. The principal reason for this is the necessity to expand earthquake catalogues back in time. The instrumental earthquake catalogue available for any region never extends further back in time than the beginning of the 20th century, and in many tectonic regimes this is far shorter than the length of the seismic cycle, and is thus unrepresentative of the long-term hazard. Depending on cultural history, it may be possible to extend the earthquake catalogue back in time for several hundred years more, giving a much more adequate data set for hazard analysis. In Italy, for example, after a long and thorough investigation of historical materials, involving professional historians as well as seismologists, there is now an excellent catalogue providing close on 1000 y of usable data. This was only possible through the application of macroseismic methods.

This project, and others like it in other countries, have also involved increased attention to the methods themselves. On the one hand, there has been much consideration of the processes involved in assigning intensity, in order to make this process as reliable as possible. On the other hand, there has been considerable interest in the subject of deriving earthquake parameters from macroseismic methods.

The focus of much of the work on improving intensity assignments has been the development of the European Macroseismic Scale, intended as a tool suitable for modern macroseismic studies, which would minimise problems of subjectivity and poor practice which have been observed in the past. One of the important advances of the EMS was the provision of methodological guidelines. Before the publication of the EMS anyone starting macroseismic investigations for the first time would find that existing intensity scales consisted of a list of diagnostics, with very little material available in print describing best practice in actually using it. The provision of detailed guidelines (and also pictorial illustrations) should go a long way to reduce inconsistencies in the use of the scale by different investigators.

At the same time, the extensive historical investigations into early earthquake descriptions have provided a large body of experience regarding the ways in which historical evidence can legitimately be treated in the assigning of intensities. The sort of bad practice often encountered in the past, such as the assigning of unqualified high intensity values to single reports of damage to anomalous structures, should be eradicated in the future. As the investigation of historical earthquakes is covered in more detail in a separate chapter of this volume, no more will be said about it here.

The increased interest in macroseismic methods for the determination of earthquake parameters has also pointed the need for modern macroseismic monitoring. Increased and improved macroseismic data sets from modern earthquakes for which good instrumental data are also available, are needed

for the purposes of calibration of macroseismic techniques. Intensity can also be used directly in seismic hazard studies as a parameter for expressing the hazard itself, in place of physical measure of ground motion like peak ground acceleration. This is not often done, since most seismic hazard studies are done to establish design values for engineers, and for this purpose physical parameters are usually required (although it was the practice at times in Eastern Europe to stipulate design levels in terms of intensity values). However, there are two reasons why intensity may be used for this purpose.

The first is that there are many parts of the world where there are abundant intensity data available, but no or few strong motion records. In such cases, the attenuation of intensity can be described quite accurately, but the attenuation of physical ground motion parameters is uncertain. By using intensity to express the hazard, a reliable hazard value can be given. However, some way then has to be found to enable engineers to use this in the design process, which might involve some conversion from intensity to other parameters, and such conversions can be contentious.

The second reason is that seismic hazard studies may be conducted for audiences other than engineers, and for whom physical parameters of ground motion are not particularly meaningful. Such groups could include insurers, planners, politicians, and ordinary members of the public. Since intensity can be related directly to earthquake effects, including damage, hazard assessments expressed as intensity values can be readily understood. Peak ground acceleration means little to an insurer unless it can be converted into damage terms, which generally it cannot be.

The introduction of intensity into hazard calculations is straightforward: in place of the usual peak ground acceleration (pga) attenuation function an intensity attenuation function is used. The only other thing that needs to be changed is the way in which scatter in the attenuation is applied; scatter in pga is generally considered to be lognormally distributed, but for intensity it is normally distributed.

It is desirable that intensity attenuation curves should be derived for normal soil conditions, and not be heavily influenced by observations where the intensity value has been increased by soil amplification. This enables a later modification of hazard values to be made due to soil conditions at site.

One objection that is sometimes raised is that intensity distributions can be highly irregular, making attenuation functions unreliable. The situation can be improved by (1) ensuring that the basic intensity assessments are of good quality; (2) not allowing the pattern to be obscured by anomalous values due to soil conditions; and (3) the use of azimuthal equations to deal with isoseismal elongation. The compilation of useful intensity attenuation curves for different parts of the world is one of the most pressing tasks toward the advancement of intensity as a tool in seismic hazard studies. It provides another reason why macroseismic studies of modern earthquakes are important. The fact that some major countries

lack coherent macroseismic monitoring programmes is regrettable, and will surely be viewed in the future as having been short-sighted.

4.2 Seismic Risk

The usefulness of earthquake intensity in seismic hazard estimation carries over into seismic risk studies in very similar ways. However, it can be considered to be even more useful, since seismic risk studies are concerned with establishing the probability of damage or loss occurring, and intensity is a direct expression of damage.

In general practice, seismic hazard is defined as the probability that a certain level of earthquake ground motion will occur at a site within a given time interval; seismic risk is the probability that some type of failure will occur due to earthquake, measurable in terms of damage, financial loss, or even casualties. Thus, whereas seismic hazard is purely a product of natural processes, seismic risk is dependent on societal exposure in terms of the built environment or human population. The fragility of structures is expressed in terms of vulnerability, and the relationship between risk and hazard can then be written in terms of a simple equation:

$$\text{Risk} = \text{Hazard} \times \text{Vulnerability} \quad (11)$$

where “vulnerability” is the probability that, given a certain level of ground motion, damage will occur. This equation is sometimes written with an additional term “Exposure,” representing the total amount of property liable to be affected.

From the point of view of the seismologist, seismic risk studies present a harder problem than seismic hazard, since data on vulnerability may not be easy to come by. A seismic hazard assessment can be conducted on the basis of knowledge of geophysics and geology; from such data one may construct a seismic hazard map of anywhere in the world. To construct a seismic risk map, one would need to know something about the distribution of buildings, and this information may be more intractable, except at a very generalised level.

However, this task is made somewhat easier by the application of earthquake intensity as a parameter of earthquake shaking, rather than the use of physical parameters such as peak ground acceleration. The use of pga or some similar parameter requires the construction of vulnerability functions relating ground motion to damage. This can be difficult, particularly with pga, which has been shown often not to correlate well with damage. One needs only to consider the very high accelerations recorded in some recent earthquakes, which have not been accompanied by particularly high levels of damage. In contrast, a modern macroseismic scale contains its own implicit vulnerability functions.

An earthquake intensity scale can be used in two different ways. The conventional use (which will be termed here the “forwards” use) is the one that most people will be familiar

with: an earthquake occurs; the seismologist goes out and examines the damaged localities. He assigns intensity values to each locality using a macroseismic scale, plots the values on a map, and, from the resulting distribution, earthquake parameters may be derived which augment those derived instrumentally. Further, the seismologist constructs an intensity attenuation equation by analysing observed intensity distributions as a function of magnitude and distance.

The second, or “backwards” use, is as follows. The seismologist projects a design earthquake that may occur some time in the future, with expected location and magnitude. From a knowledge of the regional intensity attenuation, the expected intensity at a given place can be worked out. This expected intensity value then describes the anticipated effects of the earthquake in terms of damage to buildings. Because intensity is defined by observed effects (specifically damage), an intensity attenuation equation is an expression of the expected damage distribution from any earthquake, as a function of magnitude and distance.

The attractive aspect of this from the point of view of seismic risk is that the use of physical parameters of ground motion is simply circumvented. Since the intensity attenuation function is validated in the first place with respect to observed damage, it is automatically applicable in the second case when it comes to estimated damage in the future. Why, then, is this simple and effective approach so underutilised? The most likely reason is a general distrust of intensity as being a subjective and generalised parameter, lacking in scientific precision. However, a generalised approach is sometimes exactly what is needed; a robust instrument is apposite, and an intensity scale operates at the right level for many practical purposes.

The other problem is that many workers are still applying old intensity scales in a modern environment. Most intensity-related work in the USA is still conducted using the Modified Mercalli Scale (MM) of either the Wood and Neumann (1931) or Richter (1958) versions. Both these scales, as formulated, are obsolete. The key objections are that (1) they make no allowances for the probabilistic nature of intensity, where damage is properly represented as a set of distributions; (2) they do not have the capability of dealing with modern engineered structures; and (3) they include miscellaneous diagnostics which have been shown to be inadequate indicators of intensity (Vogt *et al.*, 1994). It is likely that perceptions that intensity is an inadequate tool for modern use are to some extent coloured by a knowledge of the inadequacies of the MM scale.

Most modern data sets prepared using the MM scale are actually much better than the preceding paragraph would imply, since unofficial rules and practices have been built on to the original scale to make allowance for its deficiencies (Dewey *et al.*, 1995). In an institution with long continuity, such as the USGS, conditions are favourable for the preservation and application of wisdom gained from long

experience of assigning intensity to local data sets. This does not overcome the problem that such procedures are often not transparent to other users of the data.

Modern intensity scales such as the European Macroseismic Scale are more suitable for application in seismic risk studies. The elimination of unreliable intensity diagnostics based on experience improves the accuracy of intensity assessments. The provision of detailed guidelines reduces undesirable variations in practices from user to user, makes intensity assessment less subjective, and makes the rules used in intensity assessment transparent to the users of the data. A flexible approach to building type and vulnerability allows a wide range of buildings, including modern engineered structures, to be taken into consideration. And importantly, a modern scale needs to be probabilistic in its approach to damage; for any type (strength) of building at a particular level of intensity, damage should be considered as a distribution. It is these factors that make the EMS-98 scale, in particular, suitable for use in seismic risk studies.

Finally, four appendices are placed on the attached Handbook CD, under directory \49Musson2. They are: Appendix 1. Damage inspection form as proposed by Tertulliani *et al.* (1996/99); Appendix 2. Italian macroseismic questionnaire (Internet version); Appendix 3. Excerpt from an Italian macroseismic bulletin; and Appendix 4. Austrian macroseismic questionnaire.

Acknowledgements

The authors would like to thank Andrea Tertulliani and Edmund Fiege Weil for their assistance in compiling Section 2 and the Appendices. Tibor Zsiros helped in sorting out the correct history of the Kövesligethy papers. We would also like to thank Jim Dewey for his helpful review comments. The contribution of Roger Musson to this chapter is published with the permission of the Director of the British Geological Survey (NERC).

USGS Earthquake Moment Tensor Catalog

Stuart A. Sipkin

US Geological Survey, Denver, USA

1. Introduction

Since 1981, the US Geological Survey's National Earthquake Information Center (NEIC) has been computing moment tensor solutions for all moderate-to-large sized earthquakes. From 1981 through the first half of 1982, a moment tensor inversion was attempted for all earthquakes with a magnitude, m_b or M_S , of 6.5 or greater. From the second half of 1982 through 1994, an inversion was attempted for all earthquakes with an m_b magnitude of 5.8 or greater (5.7 for intermediate- and deep-focus earthquakes). Beginning in 1995, an inversion was attempted for all earthquakes with a magnitude, m_b or M_S , of 5.5 or greater. In the earlier parts of the catalog, completeness is compromised because of sparse station coverage for many parts of the Earth. Station coverage has steadily improved, and is mainly responsible for the ability to move the magnitude thresholds lower with time.

The solutions are published on a monthly basis in the *Preliminary Determination of Epicenters*, the *Bulletin of the Seismological Society of America*, and *Seismological Research Letters*. Annual compilations are published in *Physics of the Earth and Planetary Interiors*. These currently include solutions for earthquakes that occurred from 1980 through 2000 (Sipkin, 1986b, 1987; Sipkin and Needham, 1989, 1991, 1992, 1993, 1994a,b; Sipkin and Zirbes, 1996, 1997; Sipkin *et al.*, 1998, 1999, 2000a,b, 2002).

2. Method

The algorithm is described in Sipkin (1982, 1986b). Briefly, the inversion procedure is based on multichannel signal-enhancement theory (Robinson, 1967). In this algorithm the far-field Green's functions are the multichannel input; the observed seismograms are the desired output; and the moment-rate tensor is the convolution filter operating on the input. Because the convolution filter found is not only a signal-enhancement filter

but is also a noise-rejection filter, arrivals in the waveform that are not specifically accounted for in the Green's functions (such as those generated by near-receiver or near-source structure, other than pP and sP phases), and that are not coherent across the suite of seismograms to be inverted, are regarded as noise and do not affect the solution. In this formalism, the system of equations to be solved are in the form of a "block Toeplitz" matrix, so it can be quickly solved using recursive techniques. These techniques are equivalent to using recurrence relations in orthogonal polynomial theory. The details of these recursive techniques can be found in Robinson (1967), Claerbout (1976), or Oppenheim (1978).

This inversion technique is applied to digitally recorded broadband P -waveform data from US National Network (USNSN) and Global Seismograph Network (GSN) stations that have good signal-to-noise ratios and that are located at epicentral distances between 30° and 95° . The solution is constrained to be purely deviatoric, but not to be a pure double couple. The source depth is determined by varying the trial depth at 1-km intervals to find the focal depth that minimizes the misfit to the data. Because the P -wave forms contain both pP and sP phases, as well as direct P -wave arrivals, this procedure generally is highly sensitive to source depth. The source depth also depends somewhat on the velocity model used in the inversion. The model currently used is ak135 (Kennett *et al.*, 1995). Although this model is quite adequate for computing the effects of mantle structure, its crustal structure may be too simple. This will not affect the mechanism found but may bias the depth estimate. Experiments involving the introduction of more realistic crustal layers yield differences on the order of 2–4 km (Sipkin, 1989), smaller than the intrinsic uncertainty of 5–10 km determined using both inversions of "realistic" synthetic seismograms (Sipkin, 1986a) and comparison with a set of well-located earthquakes (Engdahl *et al.*, 1998). An advantage that using body-wave seismograms has over the use of surface waves is better resolution of source depth for shallow sources. The

inversion kernels for two of the moment tensor elements approach zero as the source depth approaches the Earth's surface. This occurs more rapidly at longer periods. Although the use of higher-frequency body waves does not eliminate this problem, it does ameliorate it.

The deviatoric moment tensor can be decomposed into a double couple and a remainder term in an infinite number of ways. We prefer the decomposition suggested by Knopoff and Randall (1970) in which the moment tensor is decomposed into a "best" double couple and a compensated linear-vector dipole (CLVD). This decomposition is preferred to decomposing the moment tensor into a major and minor double couple because it is unique, whereas there are an infinite number of major and minor double-couple combinations. In addition, the "best" double couple and CLVD share the same principal axes; the major and minor double-couples will, in general, have equivalent force systems with differing directions. Using the preferred decomposition, the moment of the "best" double couple, M_0 , is $1/2(e_1 - e_3)$ where e_1 is the largest positive eigenvalue, corresponding to the T axis, and e_3 is the largest negative eigenvalue, corresponding to the P axis. The contribution of the CLVD component to the normalized total moment, $\hat{M}_{CLVD}$, is $2|e_{\min}|/|e_{\max}|$, where $e_{\min}$ is the eigenvalue with the smallest absolute value and $e_{\max}$ is the eigenvalue with the largest absolute value. The percentage double couple is then $100 \times (1 - \hat{M}_{CLVD})$.

3. Moment Tensor Catalog

The moment tensor solutions from 1981 through 2000, along with the hypocentral parameters determined by the NEIC, are listed in the files MT.LIS and FMECH.LIS included on the attached Handbook CD. These files, as well as updates, can also be downloaded via anonymous FTP at ghftp.cr.usgs.gov in directory `./pub/momten`.

MT.LIS contains the elements of the moment tensors along with detailed event information; FMECH.LIS contains the decompositions into the principal axes and best double-couples; the file FMECH.DOC describes the various fields.

As indicated in the Section 1, the catalog is not uniform over time. Beginning in 1981, the magnitude threshold was 6.5; in the second half of 1982, the threshold was reduced to 5.8 (5.7 for intermediate- and deep-focus earthquakes); and starting in 1995, the threshold was further reduced to 5.5. Since 1981 global coverage with broadband, digitally recording seismic stations has vastly improved. The improved station coverage is mainly responsible for the ability to move the magnitude thresholds lower with time. This is reflected in the annual average number of stations used per event. From 1981 through 1991, the average number of stations per event gradually rose from approximately 8 to approximately 13. By 1995, the average number of stations had rapidly increased to

approximately 30. Since 1995 the average number of stations per event has remained at this level.

4. Moment Tensor Inversion Code

An important *caveat* is that the moment tensor source code was not originally intended for general distribution, and so is not very well documented. It is, however, included here (on the attached Handbook CD) for historical documentation purposes.

The inversion software is modular. That is, an independent program handles each step of the process. The programs are bound by a UNIX shell script. This could also be accomplished on different operating systems with a VAX/VMS command file, a DOS batch file, etc. Many of the programs are for preprocessing (filtering, winnowing, and aligning) the data. All of these modules are contained in *momten.tar.Z*. The code also refers to several library modules—source code for each is contained in compressed tar files. The routines for recursively solving the system of equations can be found in Robinson (1967). *momcon.tar.Z* contains routines for converting from one type of source description (double-couple, principal axes, moment tensor, slip vector, etc.) to another (written by R.P. Buland, some routines modified by S.A. Sipkin). *buplot.tar.Z* contains the plotting package used (BUPLOT, written by R.P. Buland), but any plotting package of choice will do.

Acknowledgments

The staffs of the USGS National Earthquake Information Center, the USGS Albuquerque Seismological Laboratory, the IDA program at the Scripps Institution of Oceanography, and the Incorporated Research Institutions for Seismology make this work possible by operating and maintaining the US National Seismograph Network and the Global Seismograph Network and its data centers. Madeleine Zirbes wrote much of the preprocessing code and made several valuable suggestions for improving the procedure. Russell Needham, Madeleine Zirbes, and Charles Bufe did most of the routine data processing.

The Earth's Interior

Thorne Lay

University of California, Santa Cruz, USA

1. Introduction

Earth is composed of minerals and metal alloys under pressure and temperature conditions that allow elastic waves with frequencies ranging from 0.0003 to 30+ Hz to transmit through the planet with relatively little deviation from linear elasticity. In other words, an initial rapid input deformation applied to near-surface rocks, such as that accompanying sudden stress release on a fault or an underground explosion, produces stress imbalances that transmit through Earth in the form of nearly elastic *P* and *S* waves that convey the nature of the source deformations to distant locations in a way that is readily decipherable. This remarkable attribute is akin to the transmission of sound waves through air, for which there is a direct correspondence between atmospheric pressure fluctuations produced at a source, say by specific oscillations of vocal cords, and those detected on our ear drums, allowing the sound to be interpreted (even if there are many echoing reverberations that travel multiple paths to our ears as well as unrelated background noise).

If the source energy is large enough, on the order of a magnitude 5.0 earthquake, elastic wave arrivals can be detected above typical ambient noise levels over the Earth's entire surface, and seismic instruments are now capable of recording the full bandwidth of ground vibrations induced by common sources. The quasi-elasticity of Earth over a wide range of ground motions combines with the predominantly concentrically layered structure of the planet to yield straightforward relationships between observations of seismic waves at various distances from a source and the properties of the deep interior of the planet. For about 100 years seismologists have been systematically accumulating global recordings of ground shaking, locating sources of elastic wave radiation, and extracting characteristics of Earth's interior from the travel times, amplitudes and waveshapes of seismic waves. Seismological models have been interpreted by mineral physicists, geochemists, and geodynamicists for many decades to infer the composition, physical state, and dynamical processes

occurring inside the planet. This effort has resulted in a remarkable understanding of our planet's interior, although many important issues have not yet been resolved. This chapter outlines some of our understanding of the Earth's interior derived from seismology.

2. Earth Stratification and Chemical Differentiation

The most fundamental approach to gleaning Earth structure from seismic waves is to measure arrival times of ground vibrations as a function of distance from the source. Seismograms from distant earthquakes are characterized by a sequence of discrete body wave arrivals followed by dispersed surface wave trains. Given networks of seismic instrumentation with relatively uniform ground motion response, it is straightforward to pick consistent arrival times of the discrete body wave phases. Triangulation procedures can be used for natural sources to determine the source location and origin time for an assumed seismic velocity model, and the arrival times can then be plotted as a function of distance from the estimated (or known, in the case of explosions) source location. When this is done on a global scale, as in Figure 1, it is apparent that coherent arrivals associated with distinct travel time branches exist, with behavior that is predominantly dependent on epicentral distance. These arrivals correspond to various portions of the *P*- and *S*-wave fronts sweeping along the surface of the Earth, with the discreteness of the arrivals indicating that simple wave front refraction at depth dominates over 3D scattering effects. This organized transmission of seismic energy through the Earth was recognized very early in the 20th century, and pioneering seismologists began the labor of identifying each travel time branch and deducing the internal structures and source radiation effects that give rise to the complexity of seismograms. The improved structures were used to provide more accurate event locations, allowing the models to be refined in a bootstrapping manner.

FIGURE 1 Arrival times of P and S seismic phases as a function of epicentral distance in the Earth for shallow earthquake sources, along with predicted travel-time curves for a radially symmetric model of P - and S -velocity variations with depth. P and S are direct phases, PcP , ScP , and ScS reflect from the core–mantle boundary, $PKiKP$ and $SKiKP$ reflect from the inner core–outer core boundary, PP , SS , PS reflect once from the Earth’s surface, and PKP , SKP , SKS , $SKKS$ are phases that traverse the Earth’s core. (From Kennett and Engdahl, 1991. Reprinted with permission from the Royal Astronomical Society.)

Given an understanding of elastic wave behavior based on the theory of elasticity that had been extensively developed in the 19th century (Chapter 8 by Udias; Aki and Richards, 1980; Lay and Wallace, 1995), it was quickly appreciated that the multibranch complexity of Earth’s travel-time curve stems largely from the existence of reflections from the surface and from a major internal boundary overlying a region of low seismic velocities in the central region of the planet. The low velocity core of the Earth was detected in 1906 by Oldham. By 1913 the depth to the boundary of the core was quite accurately established by Beno Gutenberg, and with the discovery of the inner core in 1936 by Inge Lehmann, the basic layering of the crust, mantle, and core had been established.

For a source and receiver at the surface and a 1D model of the Earth, with P or S velocities, $c(r)$, that vary only with radius, r , basic linear elasticity yields parametric equations for P or S wave travel times, T , as a function of epicentral angular distance, Δ , given by:

$$T = p\Delta + 2 \int_{r_i}^{r_0} \frac{\sqrt{\xi^2 - p^2}}{r} dr \quad (1)$$

FIGURE 2 P and S velocity as functions of depth in the Earth for the classic Gutenberg and Jeffreys–Bullen earth models. The letters indicate classic subdivisions of the interior based on behavior of the travel time curves and inferred velocity structures. Arrows highlight the low velocity zone in the Gutenberg model and the change in velocity gradient defining the transition zone onset in the Jeffreys–Bullen model (From Anderson, 1963).

$$\Delta = 2p \int_{r_i}^{r_0} \frac{dr}{r\sqrt{\xi^2 - p^2}} \quad (2)$$

where $\xi = r/c(r)$, r_i is the radius to the turning point of the seismic raypath, $p = (r \sin i)/c(r)$ is the seismic ray parameter which is constant for a given raypath, and r_0 is the radius of the sphere. These basic equations, valid for homogeneous regions of the Earth with velocity increasing smoothly with depth, can be used to build up piecewise models of the radial P and S velocity structure either by forward calculation or inversion using the Herglotz–Wiechert method (c.f., Lay and Wallace, 1995). All of the necessary information for determining $c(r)$ is provided by the observed travel time curve for waves that turn continuously in a given homogeneous region. The travel time curves must be well enough sampled that stable estimates of the slope of the travel time curve, $dT/d\Delta = p$, can be empirically measured (when seismic arrays began to be deployed in the 1960s this value could be directly estimated, greatly improving the accuracy of inferred velocity models). Internal boundaries separating homogeneous layers can be accounted for by solving boundary value problems that result in Snell’s law for raypath kinematics and in reflection and transmission coefficients for amplitudes (c.f., Aki and Richards, 1980; Lay and Wallace, 1995).

From the 1920s to 1940s, interpolated observed travel-time tables such as the Jeffreys–Bullen Tables (Jeffreys and Bullen, 1940) were used in the Herglotz–Wiechert method to produce accurate 1D seismic velocity models for the entire Earth, including the classic Jeffreys and Gutenberg models (Fig. 2).

These particular models served as standard Earth models for decades, and the J-B travel-time tables are still used in earthquake location procedures because they provide accurate predictions of P and S wave arrival times (including major surface- and core-reflected and converted phases) to within a small fraction of a percent at teleseismic ranges.

Although body wave travel-time analysis remains a primary tool for studying Earth structure, complete waveform analysis has allowed even more information to be gleaned from seismic recordings, and has unraveled the complex interference effects involved in surface waves and normal modes (see Chapter 9 by Chapman, Chapter 10 by Lognonne and E. Clevede and Chapter 11 by Romanowicz). Seismic wave amplitudes and waveforms can now be synthesized for Earth models, allowing comparison of data and synthetics. The strengths of velocity discontinuities, structure of low velocity zones, diffractions, scattering, and complex interference of multiple arrivals can be modeled and constrained by complete waveform modeling.

An example of a contemporary 1D velocity structure for the mantle and core (the thin low-velocity crust is not included) is shown in Figure 3, along with a density structure determined by matching normal mode observations (see Chapter 10 by Lognonne and Clevede), total mass and moment of inertia values, and petrological models of the interior. Seismic velocities increase systematically with depth across the mantle as in the classic models of Jeffreys and Gutenberg, but we are now aware of the existence of abrupt velocity and density increases at the 410 and 660 km seismic discontinuities. The details of the transition zone region from 410 to about 800 km were not resolved prior to the mid-1960s, but it had been recognized as early as 1926 that complexity is present at this depth in contrast to the smoother variations of seismic structure in the lower mantle (below 800 km). Near 2900 km

depth the S velocity drops to zero, indicating the fluid state of the outer core, while the P velocity drops greatly across the core–mantle boundary before increasing smoothly with depth down to the inner core–outer core boundary.

Over vast reaches of Earth the seismic velocities increase very smoothly, i.e., across the lower mantle from 800 to 2700 km depth, and across the outer core and inner core. This is a direct inference from the smooth concave-downward travel-time curves in Figure 1, with lateral variations about the mean velocity at each depth being bounded to only a few percent except in regions near boundary layers (near the Earth's surface, near the core–mantle boundary, and in sinking lithospheric slabs). Thermodynamic calculations indicate that the composition of each major subsection of the Earth may be uniform, with gravitational self-compression fully accounting for the variation in laterally averaged velocity with depth. Solid-state phase transitions in the major Earth mineral olivine provide viable explanations for the discontinuities near 410 and 660 km depth, and cosmochemical arguments and density constraints indicate that the core is predominantly made of iron. The bulk composition of the planet can be approximated by the relative abundance of refractory materials in the Sun or by the bulk composition of undifferentiated chondritic meteorites, with the mantle composition being inferred by allowing for separation of the core alloy and continental crust (for a good review, see O'Neill and Palme, 1998). Thus, the first-order characterization of the Earth is of a chemically differentiated body in which a thin veneer of light materials has segregated into the enduring continental crust, while basalt is extracted by melting from upper mantle material to produce the recycling oceanic crust, with an extensive mantle of crystalline silicates and oxides of nearly uniform overall composition overlying the molten iron-alloy core of which the center has solidified because the geotherm intersects the solidus at the inner core boundary.

If one pauses for a moment to question how much we would know about even these first-order aspects of the interior without seismology, it is clear that predictions could be made about planetary layering for a given cosmochemical model (e.g., the assumption of a chondritic abundance of major rock- and core-forming elements, with the light alloy component of the core being O, predicts a core size of 30.1 wt%, compared to an observed value of 32 wt%, Anderson and Bass, 1986), but we would not necessarily know that there is an inner core, could not preclude a very complex compositionally stratified mantle, and would not have direct means to test and refine the assumed multiphase chemical model (by matching laboratory measurements of appropriate compositions to the observed velocities and densities). As described below, further details of the seismological structure provide the key to understanding the dynamics of the interior as well, which would otherwise remain highly speculative. There is thus no question that seismology plays a major role in our understanding of Earth's interior.

FIGURE 3 The ak135 Earth model indicating P velocity, α , and S velocity, β , as well as density, ρ and attenuation (Q_{α} is the solid line, Q_{β} is the dotted line) (from Kennett and van der Hilst, 1998).

3. Crust

Earth's crust is the most important region of the interior, providing the environment, natural resources, and geological hazards that affect humanity. The complexity of structure and geological history of the continental crust are readily apparent from surface observations, providing important clues in our efforts to understand Earth's interior, however it is essential to know the structure at depth. With very sparse drilling being confined to the upper 10 km of the crust, much of our knowledge of the *in-situ* structure of the oceanic and continental crust has been provided by seismological investigations, as described elsewhere in this volume (see Chapter 54 by Mooney *et al.* and Chapter 55 by Minshall). It is again the properties of elastic waves, particularly their reflection and refraction at interfaces across which there are abrupt changes in material properties (e.g., density, compressibility, rigidity) that enables detailed models of the crustal layering and crust–mantle boundary (a seismically defined compositional boundary called the Mohorovičić or “Moho” boundary in recognition of its discoverer in 1909) to be determined by analysis of dense profiles of ground motion recordings for both natural and human-induced sources. Seismology provides information about the interface geometries, absolute seismic velocities, presence of partial melting, and structural anisotropy of the crust, which can then be interpreted in terms of rock compositions and deformation histories by comparison to laboratory measurements of field samples, accompanied by geological reconstructions.

Gross differences between oceanic and continental crustal properties were first revealed in the 1950s by a combination of refraction and gravity studies and the first analyses of Rayleigh and Love wave dispersion observations in the period range 10–70 sec. Love wave observations in particular provided compelling evidence for an average oceanic crustal thickness of about 6 km, with both Rayleigh and Love waves indicating a typical continental thickness of 35 km or so (e.g. Ewing *et al.*, 1957). Advances in computational capabilities, inverse theory, and data quality have allowed increasing resolution of internal crustal layering by surface wave inversion, culminating in the present day capabilities described in Chapters 11 (by Romanowicz) and 54 (by Mooney *et al.*). Surface waves provide relatively limited resolution models of crustal properties, involving extensive depth and lateral averaging of the actual structure, but the integral constraints from surface waves can be combined with body wave information to give reliable detailed crustal structures.

High resolution of internal crustal properties is attained by using seismic body waves with frequencies of 1–100 Hz, and even higher for very shallow imaging, accompanied by close station spacing (meters to kilometers) to avoid spatial aliasing. The data collection and processing involved in analysis of dense linear and 2D deployments of high frequency

seismographs is generally defined as the field of Reflection Seismology, with distinct strategies being needed for analysis of much sparser data sets available for sampling the deeper interior on a global scale (see chapters on crustal imaging). At intermediate levels of resolution, the methods of Refraction Seismology, the study of primary direct, reflected and head-wave arrivals traversing the crust from both natural and human-induced sources, provide constraints on the overall crustal waveguide.

Gross attributes of crustal velocity structure, thickness, and regional variations have been summarized by Christensen

FIGURE 4 Summary of crustal refraction and reflection profiling for diverse crustal regimes indicating thickness and typical *P* velocities of crustal layers (From Mooney *et al.*, 1998).

and Mooney (1995) and Mooney *et al.* (1999). Reflection and refraction studies from hundreds of locations around the world have established that there are characteristic crustal structures in distinct tectonic environments. P velocities and thickness for various crustal types are summarized in Figure 4. Note that water layer thickness is included for oceanic structures. The average P velocity of the crust is $6.45 \pm 0.21 \text{ km sec}^{-1}$, the average continental crustal thickness is about 40 km and average oceanic crustal thickness is 12.6 km, including 4.0 km of ocean water (Christensen and Mooney, 1995). A contour map of crustal thickness, including water depth, with $5^\circ \times 5^\circ$ resolution is shown in Figure 5. Seismic models of the crust like these provide a basis for petrological interpretations using

laboratory measurements of velocities in plausible crustal materials under appropriate pressures and temperatures. Christensen and Mooney (1995) summarize current inferences about crustal petrology; upper continental crust is matched by diverse lithologies including low-grade metamorphic rocks and silicic gneisses of amphibolite facies grade, middle continental crust is consistent with tonalitic gneiss, granitic gneiss and amphibolite, and lower continental crust is consistent with gabbro and mafic granulite. There appears to be increasing garnet content with depth and mafic garnet granulite comprises the lowermost crust. Localized crustal models also play a key role in unraveling tectonic histories, mountain building and extensional events, shallow volcanic processes, and basin

FIGURE 5 Mercator projection of crustal thickness for a 5° model. Extrapolations based on tectonic province and crustal age have been made (from Mooney *et al.*, 1998).

evolution, not to mention the critical role of high resolution models in oil and mineral resource exploration. Many additional details about crustal structure are given in the accompanying chapters on crustal structure. Recognizing that continental and oceanic crust have been extracted from the interior by melting processes, and that the crustal dynamics and history are manifestations of deeper seated processes, the remainder of this chapter will elaborate on the techniques and results of seismological analyses of deeper Earth structure.

4. Upper Mantle and Transition Zone

The existence of complex upper mantle structure is immediately evident from the bimodal distribution of continental and oceanic crust. Preserving highly differentiated rocks dating back more than 3.8 billion years, continental crust clearly has different relationships to its underlying upper mantle than does basaltic oceanic crust, of which very little more than 200 million years old can be found. Given only sparse direct sampling of upper mantle rocks provided by upthrust blocks and xenoliths from deep-seated magmatism, with significant chemical alteration prevalent in both environments, seismology plays a prominent role in constraining our knowledge of upper mantle structure.

The revelations of seafloor spreading in the 1960s provided a context for oceanic upper mantle as an extensive, fairly uniform composition material from which midocean ridge basalts (Ca and Na-rich pyroxene plus an Al-rich phase) are extracted by localized decompression melting in upwellings, and to which both crust and depleted upper mantle material return by subduction of oceanic slabs. Quantification of basalt petrogenesis has played a key role in developing and testing models of upper mantle composition, with the important conclusion that the upper mantle is largely peridotitic (composed of olivine $[(\text{Mg,Fe})_2\text{SiO}_4]$ and orthopyroxene $[(\text{Mg,Fe})\text{SiO}_3]$) rather than eclogitic (mainly clinopyroxene and garnets) in chemistry (e.g., Ringwood, 1975; Green and Falloon, 1998). Ted Ringwood proposed the “pyrolite” model for upper mantle composition as essentially the sum of basalt and peridotite compatible with chondritic abundances. The oceanic crust and the underlying depleted, harzburgitic mantle material are embedded in a conductive thermal boundary layer, the upper half or so of which is relatively cold ($<650^\circ\text{C}$) and stiff, yielding a mechanically competent lithospheric plate (note the distinction between thermal and mechanical boundary layers). As the temperature increases with depth, approaching the melting point of the mantle material, the thermal boundary layer undergoes transitions in mechanical integrity, with viscous lateral shearing, and in thermal transport, with the latter progressively becoming dominated by solid-state advection rather than conduction. Seismological investigations of the suboceanic mantle seek to characterize the layering of the basalt-depleted zone of the

lithosphere, to detect any strain-induced fabrics in the oceanic plate or in the strongly sheared region in the lower part of the thermal boundary layer and below it, often called the asthenosphere, and to detect any variations with depth that correspond to effects of increasing temperature and phase transitions.

For subcontinental mantle, the context of plate tectonics provides far fewer well-defined questions, and basic issues such as the thickness of the continental lithosphere, the extent of and nature of compositional depletion of the subcontinental upper mantle, and the thermal history and structure of the subcontinental upper mantle are all open questions, with seismological imaging playing a key role in characterizing the structural elements. As noted below, the distinctions between continental and oceanic upper mantle persist down to depths of 200–350 km, below which any obvious relationships between mantle structure and surface tectonic features rapidly disappear.

4.1 The Seismic Lid

In both continental and oceanic regimes, the uppermost mantle region below the Moho overlies a seismic low velocity zone. The high-velocity layer from the Moho down to the low-velocity zone is called the upper mantle “lid,” and this corresponds to the “seismic lithosphere.” (Long-term rheological behavior and seismic velocity structure need not correspond directly, for they involve factors such as time of loading, temperature, and stress; however, it is likely that a common underlying influence is the onset of partial melting which affects both seismic velocity and viscosity and defines the bottom of the seismic lid and the rheological transition from the mechanical boundary layer to the ductile asthenosphere.)

The most straightforward aspect of mantle lid velocity structure that can be determined is the velocity just below the Moho discontinuity, as this is manifested in the slope of the P_n and S_n “headwaves” along the crust–mantle boundary. Usually, a linear fit to the headwave branches is sufficient, with measured P velocities of $7.6\text{--}8.6\text{ km sec}^{-1}$ and S velocities of $4.4\text{--}5.0\text{ km sec}^{-1}$ being inferred by many studies from 1950 on (see reviews by Christensen and Mooney, 1995; Christensen and Salisbury, 1979). The average P_n velocity beneath continents is $8.09 \pm 0.2\text{ km sec}^{-1}$ (Christensen and Mooney, 1995), whereas the average oceanic P_n velocity is $8.15 \pm 0.31\text{ km sec}^{-1}$ (Christensen and Salisbury, 1979). These velocities are typical of olivine- and pyroxene-rich peridotitic upper mantle rocks from which crustal rocks have been chemically differentiated. Substantial effort has gone into mapping lateral variations in uppermost mantle velocity structure as shown in Figure 6 (e.g., Braile *et al.*, 1989; Hearn *et al.*, 1991; Hearn, 1999), with it being established that the lateral variations in velocity are associated with lateral variations in thermal structure and associated age of tectonic activity. Active rift zones tend to have low P_n velocities whereas

FIGURE 6 Contour map of P_n velocity under the United States based on many localized studies. Note the lower velocities characteristic of the tectonically active western region. (From Braile *et al.* 1989).

stable cratons and platforms tend to have higher P_n velocities. A complicating factor is that substantial seismic velocity anisotropy is observed for P_n in oceanic (Raitt *et al.*, 1969) and continental areas (Bamford, 1977), presumably as a result of plate-motion or orogenically induced alignments of the upper mantle minerals, particularly olivine. This produces azimuthal dependence of the P_n velocity, which must be accounted for when seeking an accurate seismic and petrological model for the uppermost mantle (e.g., Hearn, 1999).

The velocity structure just below the Moho generally involves slowly increasing velocity with depth, which produces a whispering gallery of phases that complicate P_n and S_n arrivals and the interpretation of the apparent velocities of these phases. Beneath some continental regions, a small abrupt increase in P and S velocity occurs near 60–90 km (e.g., Hales, 1969; Revenaugh and Jordan, 1991), possibly as a result of a phase transition from spinel to garnet facies in aluminous peridotite. This feature is detected in regional travel-time curves as well as in near vertical reflections. This uppermost mantle region is highly heterogeneous from region to region, largely as a result of chemical and thermal variations in the oceanic and continental lithosphere. In fact, the strongest lateral variations in upper mantle structure are found at mantle lid depths from 50 to 100 km, with greater than 10%

variations in S velocity and several percent variations in P velocity. Continental regions appear to have end-member lid structures associated with stable cratonic and platform regions with relatively high sub-Moho S velocities of $4.7\text{--}4.8\text{ km sec}^{-1}$, and P velocities of $8.2\text{--}8.4\text{ km sec}^{-1}$, whereas tectonically active areas have S velocities of around 4.3 km sec^{-1} and P velocities around 7.9 km sec^{-1} . This large variation is believed to be a combined thermal and compositional effect, as cratonic lid is both thicker (150–200 km) and chemically distinct from tectonically active continental lid (which may be only as thick as the crust in active rift environments). There is evidence for significant small-scale heterogeneity in the lid structure, primarily in dense long-range profiles collected in Eurasia, so the average properties given above are likely oversimplified (e.g., Ryberg and Wenzel, 1999). Oceanic regions show systematic increases in lid thickness with plate age, presumably as a result of progressive cooling of the oceanic lithosphere. This has been most systematically characterized by regionalized or tomographic inversions of surface-wave dispersion measurements (see below). Relatively simple thermal models for aging oceanic lithosphere appear to provide a viable basis for characterizing first-order radial and lateral structure of oceanic uppermost mantle lid structure (e.g., Zhang and Lay, 1999).

4.2 The Seismic Low-Velocity Zone

The presence of an upper mantle low-velocity zone is of profound importance for mantle dynamics, as it is commonly associated with a zone of partial melting, strong seismic wave attenuation, and low viscosity. Based on the body wave travel time and amplitude evidence accumulated by Beno Gutenberg for a decrease in velocity below about 60–80 km depth followed by a gradual increase commencing near 100–150 km (Gutenberg and Richter, 1939; Gutenberg, 1948, 1959) it has long been accepted that there is an upper mantle low velocity zone of some type (see the Gutenberg model in Figure 2). Low-velocity zones tend to be difficult to detect and to quantify due to the downward refraction of seismic energy that they cause. The upper mantle seismic low velocity channel is commonly associated with the asthenosphere, a rheologically defined region with strong ductile deformation and possibly partial melting underlying the lithosphere. The onset of the low velocity channel is sometimes characterized by an abrupt velocity decrease [labeled by Revenaugh and Jordan, 1991, as the “G” (for Gutenberg) discontinuity at about 80 km depth]. This relatively sharp feature is typically found in tectonically active regions and under oceanic crust, but in some cases there is a somewhat deeper low velocity zone found under cratons and platforms, which may or may not have an abrupt onset.

Early surface wave dispersion studies of the 1950s indicated that Love and Rayleigh wave-dispersion curves beneath oceanic and continental regions tend to converge for periods longer than about 75 sec and that Rayleigh wave group velocities for “mantle wave” periods of 75–400 sec have an Airy phase minimum near 225 sec that suggests the presence of a decrease in shear velocity with depth in the upper mantle (e.g., Ewing and Press, 1954; Ewing *et al.*, 1957). As inversions for models with multiple layers became viable by the early 1960s a common feature of separate fits of dispersion curves for Love and Rayleigh waves was the presence of a low velocity zone in the upper mantle. Highly precise measurements of great-circle data (multiple passages of the same wavetrain past a given station) began to resolve systematic differences for paths under oceanic, tectonically active continent, and stable continent regions for periods longer than 75 sec (e.g., Anderson and Toksöz, 1963; Toksöz and Ben-Menahem, 1963; Toksöz and Anderson, 1966; Kanamori, 1970), allowing the first attempts at pure-path regionalizations based on percentage path lengths in each tectonic province. Isotropic inversions of the dispersion curves in the range 75–300 sec yielded shear velocity models with low-velocity zones between 80 and 200–350 km depth. An upper mantle lid overlying a low velocity zone with shear velocities of 4.0–4.2 km sec⁻¹ with deeper strong positive velocity increases was a common feature of almost all surface-wave inversions of this generation. The regionalized dispersion measurements also suggested that velocity structures

under old cratons differ from those under oceans and tectonically active continental regions down to depths exceeding 250 km (e.g., Kanamori, 1970).

However, an important problem was recognized quite early on, as it proved difficult to simultaneously fit precise global and pure-path Love and Rayleigh-wave observations by isotropic models (McEvelly, 1964; Anderson, 1966). This became known as the Love–Rayleigh discrepancy, and it motivated the development of anisotropic models for upper mantle structure (Anderson, 1961; and see Chapter 53 by Cara). The inclusion of anisotropy directly affects the magnitude and nature of the low-velocity zone structure obtained by fitting surface-wave dispersion curves (e.g., Anderson, 1966; Anderson and Dziewonski, 1982). A basic requirement of most laterally and azimuthally averaged dispersion observations is that the *SV* velocity structure of the upper few hundred kilometers of the mantle is a few percent slower than the *SH* velocity structure, and initially this was addressed for regionalized data sets by performing separate isotropic inversions for the *SV*-sensitive Rayleigh waves and the *SH*-sensitive Love waves (e.g., Forsyth, 1975; Schlue and Knopoff, 1977, 1978; Yu and Mitchell, 1979; Mitchell and Yu, 1980). These pseudo-isotropic studies conclusively documented the need for extensive anisotropy of either the lid or the low-velocity zone, but it was subsequently shown that it is important to perform a self-consistent inversion for an anisotropic medium to obtain accurate models (Anderson and Dziewonski, 1982; Regan and Anderson, 1984).

From the early 1980s on, most surface-wave and normal-mode models have allowed for at least a transversely isotropic structure in the upper mantle, with five elastic constants, and this complexity was incorporated into the Preliminary Reference Earth Model (PREM) produced by Dziewonski and Anderson (1981). In PREM, which has served as the background reference model for many subsequent surface-wave tomographic inversions, making them intrinsically transversely isotropic, the horizontal propagating *S* velocity (V_{SH}) is faster than the vertically propagating *S* velocity (V_{SV}), and the horizontally propagating *P* velocity (V_{PH}) is faster than the vertically propagating *P* velocity (V_{PV}) in the upper 220 km of the mantle (Figure 7). In this model, the low-velocity zone is very subdued, and it is not necessary to have very low shear velocities as found in earlier isotropic and pseudo-isotropic inversions.

The parameterization of PREM incorporates a very strong velocity discontinuity near 220 km depth, as has been reported in several continental *P* and *S* wave travel-time studies (e.g., Lehmann, 1959, 1961; Hales *et al.*, 1980; Drummond *et al.*, 1980; Anderson, 1979). This feature, often called the Lehmann discontinuity, was suggested by Lehmann (1959) to correspond to the bottom of the low-velocity zone, a notion that was embraced in the parameterization of PREM. However, this feature is not observed globally, and appears to be primarily

FIGURE 7 Anisotropic upper mantle P velocity (V_P) and S velocity (V_S) for the transversely isotropic, 1 Hz version of the Preliminary Reference Earth Model (PREM), along with density structure (ρ) and the anisotropic parameter η . Dashed lines are the horizontal components of velocity (from Dziewonski and Anderson, 1981).

a subcontinental feature of limited extent, confined to shield and platform regions that do not have strong low-velocity zones or G discontinuities (e.g., Shearer, 1991; Revenaugh and Jordan, 1991). A viable interpretation of the continental 220 km feature is that it corresponds to a critical temperature (about 1200°C) transition from the anisotropic subcontinental mantle to the more isotropic structure below (Revenaugh and Jordan, 1991; Gaherty and Jordan, 1995), possibly embedded within a 300–400 km thick continental root (see below). However, there is evidence for a reflector near 220 km in the vicinity of some subduction zones, which cannot be accounted for by this particular model (e.g., Vidale and Benz, 1992; Zhang and Lay, 1993), so uncertainty in the interpretation of this structure remains.

The modern generation of shear-wave models for oceanic upper-mantle derived from waveform modeling of multimode Rayleigh waves, body waves, or complete body/surface waveforms show relatively pronounced low-velocity zones between 80 and 300 km (Fig. 8), even when transverse isotropy of the lid and low velocity zone is included in the modeling (e.g., Gaherty *et al.*, 1996). Both P -wave and S -wave models obtained by body wave travel-time and waveform modeling for upper mantle triplication distances (10–30°) usually include upper mantle low-velocity zones, although the resolution of such structures is limited (e.g., Grand and Helmberger, 1984; Zhao and Helmberger, 1993). Thus, it appears that the seismic low-velocity zone does exist, but is

highly variable in its properties depending on tectonic region. Rather than terminating in an abrupt discontinuity as in the PREM model, the low-velocity zone is typically underlain by a relatively steep velocity gradient with depth that persists down to the mantle transition zone. Generally this region from about 200 to 400 km depth has little structure in average Earth models (see Figs. 3 and 7). There is evidence for localized P and S velocity increases near 310 km depth in the vicinity of subduction zones (e.g., Hales *et al.*, 1980; Revenaugh and Jordan, 1991; Zhang and Lay, 1993; Zhang, 1994), but this structure is either significantly variable in depth or spatially intermittent, based on analysis of SS precursors by Shearer (1991, 1993). Revenaugh and Jordan (1991) label the 310 km feature (actually found in ScS reverberation coda at depths ranging from 275 to 345 km) the “X” discontinuity, and, lacking any explanation in terms of standard upper mantle mineralogy, they propose that it is associated with phase reactions in extensively hydrated mantle surrounding zones of extensive subduction.

4.3 The Transition Zone

The region of relatively strong positive velocity gradients below the low-velocity zone is abruptly punctuated by a global velocity increase near 410 km depth, marking the onset of the transition zone which extends from 410 to 800 km. Early body-wave velocity models of Sir Harold Jeffreys in the 1940s

FIGURE 8 Oceanic upper mantle shear velocity structures from waveform modeling studies. Note the presence of a well-developed low velocity zone (from Gaherty *et al.*, 1996).

(see Fig. 2) incorporated a change in velocity gradients above and below 400–500 km depths (based on the so-called 20°-discontinuity first pointed out by Byerly, 1926), but the detailed structure of the transition zone from 410 to 800 km depth only began to be worked out in the 1960s. Modeling of long-period surface-wave dispersion curves first indicated that the upper mantle low-velocity zone is globally underlain by strong positive velocity gradients near 350–450 km and 600–700 km depths (e.g., Anderson and Toksöz, 1963; Toksöz and Ben-Menahem, 1963; Toksöz and Anderson, 1966). This focused attention on body-wave travel-time and apparent-velocity measurements from newly deployed regional seismic arrays for the distance range of 1000–3000 km, and it was soon recognized that two major upper mantle travel-time triplications are produced by abrupt *P* and *S* velocity increases near 410 and 660 km depths (e.g., Niazi and Anderson, 1965; Ibrahim and Nuttli, 1967; Johnson, 1967; Kanamori, 1967). Anderson (1967a) attributed these rapid velocity increases to solid–solid phase changes of $(\text{Mg,Fe})_2\text{SiO}_4$ olivine to β -phase (modified-spinel structure) and γ -spinel to more compact oxides, respectively. The precise nature of the post-spinel transformation was not worked out for several years and it

is now known to involve a disassociative transformation to the silicate perovskite phase of MgSiO_3 plus magnesiowüstite $(\text{Mg,Fe})\text{O}$ (e.g., Liu, 1976; Ito and Takahashi, 1989; Bina and Helffrich, 1994). The combination of seismological constraints and experimental measurements which has established that these phase transitions in olivine are responsible for the two major upper-mantle discontinuities codified the earlier inferences by Francis Birch and J.B. Thompson that phase transitions were responsible for the zone of steep velocity gradient in Jeffreys' velocity model (Fig. 2) between 400 and 1000 km depth (Birch, 1952). Although there had been suggestions of transition-zone discontinuities dating back to Byerly (1926), global seismic velocity models did not incorporate the 410 and 660 km discontinuities until the surge of observations in the mid-1960s demonstrated their global existence and placed bounds on the depths and velocity increases that are involved.

Throughout the last three decades, numerous seismological procedures have been developed to extract increasing information about the velocity structure in the transition zone. A combination of wide-angle triplication studies and near vertical top-side and bottom-side reflection and conversion studies have yielded extensive information about the contrasts in velocity and density, sharpness (depth extent of the velocity increases), and topography of the 410 and 660 km discontinuities. The process is complicated by the fact that there are strong variations in the lid and low velocity zone structure above the discontinuities, as well as by limitations imposed by the distribution of seismic stations and sources.

Wide-angle triplication studies exploit the complexity of the *P*- and *S*-wave travel-time curves in the so-called "upper mantle" distance range of 12°–30°. This is illustrated in Figure 9, for a *P* velocity model appropriate for the western United States (Walck, 1984), where there is a thin lid and shallow low-velocity zone. As it encounters rapidly increasing velocity with depth the wavefront folds over on itself, with energy that turns above, at and below a discontinuity being refracted to each distance in the associated triplication range. The transition zone discontinuities produce abrupt changes in the slope of the first arrival branch, and the ray parameters for each of the three arrivals of the triplications are different enough that they can be measured, as long as secondary arrivals are recognized amidst the coda generated by the first arrival (Fig. 9). The velocity structure can be determined by matching the timing and amplitudes of the arrivals in the triplication range, as well as by matching the corresponding ray parameter measurements. The origin of the "20°-discontinuity" notion is readily apparent in the overall curvature of the first arrival time curve resulting from energy turning in the much different velocities above and below the transition zone.

Dense sampling of the travel-time curve and recognition of secondary arrivals as triplication branches is required in order to establish that discontinuities are present, and

FIGURE 9 (a) A P -wave velocity model found for the tectonically active upper mantle below the Gulf of California. The observed and predicted travel times for this region are shown in (b) and observed and predicted ray parameter values are shown in (c) (modified from Walck, 1984. Reprinted with permission from the Royal Astronomical Society).

typically only limited quantification is possible by classical travel time and ray parameter modeling alone. Waveform modeling methods developed in the late 1960s and throughout the 1970s (e.g., Helmberger, 1968; Helmberger and Wiggins, 1971; Fuchs and Müller, 1971; Chapman, 1976, 1978; Richards, 1973) enabled complete synthesis of the triplication waveform interference and relative amplitudes for 1D, and later 2D structures (e.g., Chapman and Drummond, 1982; Helmberger *et al.*, 1985). With these powerful tools, dozens of wide-angle studies of mantle structure have been carried out, resulting in regionalized velocity structures extending down through the transition zone. Nolet *et al.* (1994) consider the evidence for lateral mantle heterogeneity based on comparison of upper mantle models derived by modeling short-period P , long-period P , and long-period S triplications (Fig. 10). Additional shear-wave models for oceanic areas are shown in Figure 8. The majority of these models have been developed assuming isotropic transition zone structure (the data typically provide too little information to constrain anisotropic structure, but the fact that the data can be well modeled by isotropic models suggests that transition zone anisotropy is probably not very large, if present at all). Note that there are pronounced differences in lid structure, in structure of the low velocity zone, and in structure near 220 km depth, as discussed previously. Some of the variations may result from approximating laterally heterogeneous structure with 1D models. However, all models show 410 km and 660 km discontinuities, and it is accepted that these are globally present as expected for phase transformations of a primary mantle component.

There are apparently significant variations in size and sharpness of the velocity increases. Wide-angle triplication modeling is typically not sensitive to density structure, but the nearly factor of 3 variation in P -velocity jump at 410 km depth seen in these models may be influenced by failure to account for topography on the boundary. The S -velocity jump at 660 km in most models is about 7–8%, and appears to be stronger than that at 410 km (5%), whereas the P velocity contrasts are more similar, averaging 5–6% at 410 km and about 4% at 660 km [Estabrook and Kind (1996) present evidence for a P -velocity jump of only 2% at 660 km]. Very strong evidence for an even stronger jump of as much as 10% in S velocity at 660 km depth, along with reduced density jumps of 4–5%, has recently emerged from the systematic study of underside reflections as a function of angle of incidence (Shearer and Flanagan, 1999) and from amplitudes of top-side conversions (Castle and Creager, 2000). The velocity contrasts at the discontinuities provide a means for assessing the relative abundance of olivine component (for which the contrasts in velocities and densities across phase transformations can be measured in the laboratory) in the transition zone. The observed jumps are smaller than expected for a purely olivine mantle, so it is believed that there is significant presence of orthopyroxene, garnet, and/or clinopyroxene (with the latter two possibly giving an eclogitic component) that “dilute” the percent-wise velocity increases (e.g., Bass and Anderson, 1984; Anderson, 1991). The estimates of large shear-velocity contrast tend to favor an olivine-rich composition of the transition zone. Because there is nonuniqueness in possible mixed compositions that can match the velocities and

(From Nolet *et al.* 1994.)

densities, details of the bulk chemistry of the transition zone are still unresolved. The possibility that the 660-km discontinuity coincides with a chemical contrast as well as (or instead of) the spinel to perovskite transformation in olivine

has been discussed for decades, but it appears possible to fully account for the discontinuity by the phase transition. This still does not preclude the possibility that the bulk composition of the lower mantle differs from that of the transition zone as discussed later.

There is a relatively steep velocity gradient between the two major transition zone velocity discontinuities, with a few models indicating rapid P or S velocity increases near 520 km depth (Fig. 10). Most S -wave models, and some P -wave models indicate a zone of steep velocity gradient extending down from the 660 km discontinuity to about 800 km depth, below which there is a reduced velocity gradient extending smoothly into the lower mantle. This feature is incorporated into recent average Earth models such as PREM (Fig. 7), IASP91 (see iasp91 in Fig. 10) and ak135 (Fig. 3). I take 800 km depth as the lower boundary of the transition zone, for the seismic models generally show only smooth velocity gradients at larger depths and the primary-phase transitions expected for major components of the upper mantle and transition zone should be completed by this depth. However, there is evidence for nonglobal discontinuities at 900 and 1200 km depth as well as deeper transitions in the spectrum of lower mantle lateral heterogeneity (see below), so there may be further localized phase transitions or chemical contrasts at greater depths.

Analyses of converted and reflected waves also constrain properties of the transition zone discontinuities. The first such phases to be exploited were precursors to PKPPK (P'P' precursors), involving underside reflections from transition zone discontinuities observed near angular distances of 70°. These near-vertical incidence reflections are particularly sensitive to the sharpness and impedance contrast across the boundary, and were first used to constrain properties of the 410 and 660 km boundaries by Adams (1968, 1971), Engdahl and Flinn (1969) and Whitcomb and Anderson (1970). These phases have subsequently been extensively studied over the years, providing limited sampling of different mantle regions and revealing stronger reflections for 1 Hz signals from the 660 km boundary than the 410 km boundary (e.g., Nakanishi, 1989; Benz and Vidale, 1993). This requires a sharp 660 km impedance contrast, no broader than about 4 km in many areas. In some cases the 410 km feature also gives strong 1 Hz reflections (e.g., Benz and Vidale, 1993; Vidale *et al.*, 1995; Helffrich and Wood, 1996; Neele, 1996), but often it does not, implying that in some regions the 410 km feature may be spread over more than 5 km thickness or is subject to strong lateral variations or small-scale topography. The olivine to β -phase transition may have nonequilibrium effects (e.g., Solomatov and Stevenson, 1994), nonuniform rate of velocity increase with depth (e.g., Bina and Helffrich, 1994; Stixrude, 1997) or complexity due to accompanying gradual transformations of garnet-pyroxene components.

There are many additional top-side and bottom-side reflections and conversions from the mantle discontinuities

that can be sought in order to constrain their properties. P waves convert to S waves (Pds) at boundaries under a station, arriving in the coda of direct P , and these can be stacked for arrays of sources to quantify the weak phases (e.g., Vinnik, 1977; Stammer *et al.*, 1992; Dueker and Sheehan, 1997; Gurrola and Minster, 1998; Bostock, 1998; Chevrot *et al.*, 1999). S waves convert to P at boundaries below a station, giving rise to Sdp arrivals that precede direct S (e.g., Bath and Stefánson, 1966; Jordan and Frazer, 1975; Faber and Müller, 1980; Bock, 1988). S waves from deep slab events convert to P waves (SdP) at boundaries below the sources, arriving in the P -wave coda (e.g., Bock and Ha, 1984; Vidale and Benz, 1992; Wicks and Richards, 1993; Niu and Kawakatsu, 1995; Castle and Creager, 1998a), with these phases being particularly useful for determining properties of mantle discontinuities below subducting slabs. Upgoing P and S phases from deep slab events reflect from the underside of boundaries and are observed at large distances (pdP , sdS), providing a means to image properties of mantle discontinuities above deep sources (e.g., Vidale and Benz, 1992; Zhang and Lay, 1993; Flanagan and Shearer, 1998b). Near vertical ScS reverberations generate a suite of top- and bottom-side reflections from mantle discontinuities which can be stacked to image impedance contrasts and depths (e.g., Revenaugh and Jordan, 1991a,b; Clark *et al.*, 1995). Top- and bottom-side reflections also produce a suite of arrivals between P and PP and between S and SS which can be

detected and identified by stacking of multiple observations (e.g., Shearer, 1991).

The most important of these boundary interactions phases have been the underside reflectors that are precursors of PP (PdP) (e.g., Bolt, 1970; King *et al.*, 1975; Shearer, 1991; Neele and Snieder, 1992; Estabrook and Kind, 1996; Shearer and Flanagan, 1999) or SS (SdS) (e.g., Shearer, 1990, 1993; Petersen *et al.*, 1993). These phases provide much more extensive coverage of mantle discontinuities than most other phases, allowing global maps of topography on the boundaries to be determined (e.g., Shearer and Masters, 1993; Shearer, 1993; Estabrook and Kind, 1996; Flanagan and Shearer, 1998a). Figure 11 shows 10° radius cap-averaged values of depths to the “410-km” and “660-km” boundaries obtained from SS precursors, corrected for an upper mantle shear-velocity model. The mean depths of the two main upper mantle discontinuities are 418 km and 660 km. Although there are concerns about biases in these estimates from unresolved small-scale topography (Neele *et al.*, 1997), relatively large-scale coherent regions appear in the topographic maps. Increased depths to the 660 km feature are found in circum-Pacific regions of current and past subduction, supporting the notion that the boundary is associated with the endothermic γ -spinel to perovskite phase change and that subducting slabs deflect and produce broad cool features near this boundary. This is also consistent with studies of localized boundary deflections near slabs (e.g., Richards and Wicks, 1990; Wicks

FIGURE 11 Cap-averaged estimates of topography on the “410-km” discontinuity, the “520-km” discontinuity, the “660-km” discontinuity and the transition zone thickness between the “410” and “660” discontinuities, based on underside reflections that arrive ahead of SS . The estimates have been corrected for surface topography, crustal thickness, and upper mantle shear wave velocity structure beneath the SS bounce points (from Flanagan and Shearer, 1998).

and Richards, 1993; Niu and Kawakatsu, 1995; Vidale and Benz, 1992; Castle and Creager, 1997, 1998b). At long wavelengths the 660 km feature varies in depth by 35–40 km, which is far less than would be expected if the boundary were a compositional contrast. Topography of the 410 km feature is smaller in amplitude (20–25 km) and globally uncorrelated with the 660 km feature [although Revenaugh and Jordan (1991a) present evidence for anti-correlation of the two in some regions]. The olivine to β -phase transition that is associated with the 410 km discontinuity is exothermic, and should be elevated in the vicinity of cold slabs, however, conflicting results have been reported on the near-slab topography of this feature (e.g., Vidale and Benz, 1992; Zhang and Lay, 1993; Collier and Helffrich, 1997; Flanagan and Shearer, 1998b). A complicating factor is that the transformation of olivine may be kinetically inhibited, with untransformed material penetrating well below 410 km (e.g., Sung and Burns, 1976; Rubie and Ross, 1994). The complex thermal structure and kinetic effects near subducting slabs probably result in a rather poor reflector. The fluctuations in distance between the 410 and 660 km features shown in Figure 11 show a pronounced contrast between central Pacific and circum-Pacific regions, but no average difference between continents and oceans. In contrast, Gossler and Kind (1996) have proposed that the discontinuity separation is actually larger under continents, favoring very deep roots of continents.

Long-period *SS* precursors are also extensively observed to originate near a depth of 520 km (e.g., Shearer, 1990, 1996; Flanagan and Shearer, 1998a), and the topographic variations of this reflector can also be imaged (Fig. 11). *ScS* reverberations also consistently show a weak arrival (Revenaugh and Jordan, 1991a). A shear-wave impedance contrast less than half of that found for the 410 km feature is involved, so although the 520 km boundary is probably global in extent, it may produce arrivals below noise levels in some sparsely sampled regions. It is likely that this feature is associated with transformation from β -phase to γ -spinel (e.g., Rigden *et al.*, 1991), which is not expected to produce a very sharp feature in seismic velocities, but should produce a several percent increase in density. As noted previously, several upper mantle *P*- and *S*-wave models obtained by modeling of wide-angle triplications incorporate some increase in velocity gradient near this depth (e.g., Helmberger and Wiggins, 1971; Helmberger and Engen, 1974; Mechie *et al.*, 1993), however many long-period models do not require any velocity structure at this depth, and several studies of short-period *P* waves indicate that no sharp increase in *P* velocity is present (e.g., Jones *et al.*, 1992; Cummings *et al.*, 1992; Benz and Vidale, 1993). This set of observations can be reconciled by the existence of a several percent contrast in density, with little *P*-velocity or *S*-velocity increase, with more than 50% olivine component in the transition zone, which favors an olivine-rich pyroclitic

mantle model without much eclogite in the transition zone (Shearer, 1996).

There is also evidence for an impedance contrast near 705–770 km depth, imaged most extensively by *ScS* reverberations (Revenaugh and Jordan, 1991a,b), but with some evidence from wide-angle *P* waves (e.g., Datt and Muirhead, 1976; Muirhead and Hales, 1980) and in *P'*/*P'* precursors (Sobel, 1978). Although this is not established as a global boundary, it is perhaps closely linked to the bottom of the zone of steep velocity contrast in many *S*-wave models which does appear to have global extent (Fig. 10). The ilmenite to perovskite transformation (Liu, 1977) is a viable candidate for the impedance contrast when it is present (Revenaugh and Jordan, 1991a), which should be in relatively cold (slab-related?) mantle, while gradual transformations of majorite and garnet to perovskite may account for the ubiquitous steep gradient just below the 660 km discontinuity (e.g., Anderson, 1991).

The principal components of upper mantle and transition zone structure are summarized in the schematic in Figure 12. Continents and oceans have significant differences extending from the crust to depths near 350 km (see below), oceans have pronounced shallow low shear velocity layers, there are global discontinuities near 410 km, 520 km and 660 km depth, with temperature variation-induced topography on these boundaries compatible with their interpretation as phase transitions in the olivine component of the mantle. There are intermittent discontinuities associated with continental crust, the vicinity of subduction zones, and the base of the transition zone. All of these features, revealed by seismology, provide a basis for testing and refining models of the composition and state of the upper mantle and transition zone.

4.4 Tomographic Models of the Upper Mantle and Transition Zone

The foregoing discussion has addressed average upper mantle and transition zone structure, with some attention paid to bimodal distinctions between continental and oceanic regions. Given the complexity of Earth's history, with its ongoing dynamical motions, it would be surprising not to find complex lateral variations in structure everywhere in the mantle, which need not be directly coupled to surface geology. The variety of localized 1D models seen in Figure 10 strongly indicates that this is the case. From the early efforts at simple tectonic regionalizations for interpreting great-circle dispersion measurements (e.g., Toksöz and Anderson, 1966; Kanamori, 1970) methods of seismic tomography (see Chapter 52 by Curtis and Snieder) have been developed to image lateral variations relative to a reference Earth model for scales extending from borehole measurements, to crustal features, to lithospheric scales, to global 3D inversions. Seismic tomography, although commonly involving approximations to the

FIGURE 12 Schematic of upper mantle structural variations ranging from continental shield to ocean environments. Major velocity discontinuities are the crust-mantle Moho boundary (M), a continental velocity increase near 80 km depth (H), an oceanic velocity decrease at the base of the oceanic lid (G), a stable continental feature near 200 km (L), an intermittent discontinuity observed near subduction zones (X), and the global structures near 410, 520, and 660 km, as well as a less pronounced feature near 710 km. Cold temperatures near subducting slabs can elevate or depress the phase boundaries at 410 and 660 km, respectively (from Revenaugh and Jordan, 1991b).

propagation effects, is generally applied with few, if any, explicit *a priori* constraints on the structure to be imaged (aside from resolving lengths explicit in the model parameterization), allowing unexpected features to be detected. This enables seismology to characterize the structural elements of complex dynamical systems such as magmatic centers, plumes, subducting slabs, and mantle convective systems. Indeed, the applications are now vast in number, and extensive reviews and books are available providing extensive details about the methodology and results (e.g., Thurber and Aki, 1987; Nolet, 1987; Romanowicz, 1991; Iyer and Hirahara, 1993; Ritzwoller and Lavelle, 1995). Without the seismic imaging tool, most of our understanding of dynamical features in the mantle would simply involve conceptual cartoons.

The basic concept of seismic tomography is to use extensive raypath coverage through a given volume of rock to infer heterogeneous properties of the medium such as 3D velocity or attenuation structure. Typically, arrival-time measurements (or amplitudes) for each path are converted into anomalies with respect to predicted times (amplitudes) computed for a background reference model using estimated (or known, in the case of explosions) source origin parameters. The measured anomalies are treated as path integral effects, and are projected onto a spatially parameterized version of the medium, with basis functions in the form of blocks, spherical harmonics, splines, or other general representations. The

spatially varying parameters in the medium are inverted for by matching the observations subject to various constraints (smoothness of the medium, designated levels of variance reduction, etc.) with the cross-consistency between paths constructing the image of the heterogeneity (see Chapter 52 by Curtis and Snieder for mathematical details). The resulting images tend to improve in reliability with more uniform ray-path sampling of the medium, larger data sets that reduce random errors, improved constraints on source locations, and iterative or nonlinear inversion methods that include the ray-path perturbations and fresnel-zone sampling of the medium as the model changes.

Although there had been many earlier studies of velocity heterogeneity in the crust and mantle on various scales, the first (initially reported in 1974) formal application of seismic tomography without *a priori* tectonic regionalizations was to image the lithospheric structure beneath large seismic arrays, where fluctuations in relative arrival times over small distance separations provide constraint on the structure under the array (e.g., Aki and Lee, 1976; Aki *et al.*, 1976, 1977). This led to many inversions for structure under arrays, yielding an understanding that there is small-scale (1–100+ km) velocity heterogeneity almost everywhere in the upper mantle, as reviewed by Aki (1982). In parallel, arrival-time bulletins for large numbers of body waves were also applied to regionalized imaging of mantle downwellings (e.g., Hirahara,

1977; Humphreys *et al.*, 1984) or global mantle P velocity structure (e.g., Sengupta and Toksöz, 1976; Dziewonski *et al.*, 1977; Comer and Clayton, 1983; Dziewonski, 1984). New methods were introduced for solving large matrix problems with as many parameters as necessary for full 3D descriptions of the heterogeneity in the mantle, even when only large-scale structures are allowed for. Rapidly accumulating databases of digital seismic waveforms were also being processed, primarily measuring surface-wave dispersion or free oscillation eigenfrequencies for unprecedented numbers of paths, and these data were also incorporated into inversions for aspherical mantle structure (e.g., Masters *et al.*, 1982; Nakanishi and Anderson, 1982, 1983; Woodhouse and Dziewonski, 1984; Tanimoto and Anderson, 1984).

The first generation of global tomographic models established that surface geology and tectonics are clearly manifested in the velocity heterogeneity of the upper 200 km of the mantle (see Fig. 13). Relatively low velocities underlie major upwellings such as midocean ridges and continental rifts (e.g., the Red Sea), systematic increases in velocity are associated with the thickening thermal boundary layer underlying aging ocean crust, low upper mantle velocities are found under continental regions with active tectonic deformation (e.g., the western US), and all large continental cratons have relatively

high velocities which may extend as deep as 400 km. The resolution of these early models was only on the order of 5000 km, but it was established that there is strong power in the heterogeneity spectrum at long wavelength, partly as a result of the distribution of continents and ocean, as well as the scale of oceanic plates.

The current generation of tomographic models for the mantle and transition zone have built on these early results, with many advances in data quantity, wave-propagation theory, and types of measurements used in the inversions. P -wave arrival times and fundamental mode surface wave observations have been supplemented by many secondary body-wave arrivals (e.g., PP , PcP , PKP , $PKIKP$, S , SS , SSS , ScS , SKS) and by higher mode surface waves and split multiplets in the free oscillation spectrum (see Ritzwoller and Lavelle, 1995, for extensive references). The numbers of waveforms used for surface-wave inversions have grown to 50 000 and more (e.g., Zhang and Lay, 1996; Trampert and Woodhouse, 1996; Ekström *et al.*, 1997; Laske and Masters, 1996; Boschi and Dziewonski, 1999), and vast body-wave arrival-time data sets have been reprocessed and screened for high quality data (e.g., Engdahl *et al.*, 1998). Global resolution has been improved significantly in the upper mantle, with models having been presented that achieve (or purport to

FIGURE 13 An early global shear velocity structure obtained by seismic tomography. This shows the relative perturbations of shear velocity at a depth of 150 km in model M84C. Relatively high velocities underlie old oceanic regions as well as continental regions, while relatively low velocities tend to locate under midocean ridges and in back-arc basins (from Dziewonski, 1989).

achieve) 500–1000 km scale resolution globally (e.g., Inoue *et al.*, 1990; Zhang and Tanimoto, 1991; Vasco *et al.*, 1995; Zhou, 1996; Trampert and Woodhouse, 1996; Ekström *et al.*, 1997; Grand *et al.*, 1997; van der Hilst *et al.*, 1997; Boschi and Dziewonski, 1999; Bijwaard, *et al.*, 1999; Ritsema *et al.*, 1999). For the upper mantle there is quite good compatibility between global shear-velocity models expanded in spherical harmonic degrees up to about degree 12–16 (e.g., Masters *et al.*, 1996; Li and Romanowicz, 1996; Su *et al.*, 1994, 1997), and images for a representative recent model are shown in Color Plate 20. This figure shows: improved resolution of the high-velocity structures under continents, which persist to depths greater than 300 km; low velocities at large depths under the fast-spreading mid-Pacific ridge, but not under the slow-spreading mid-Atlantic ridge; a strong decline in velocity fluctuations from the upper mantle to the transition zone, with the latter showing high-velocity features due to slabs in some regions as well as a few localized low-velocity regions under the Pacific. The heterogeneity is still dominated by long-wavelength structure, so the contrast relative to earlier models (see Fig. 13) is not very dramatic.

Higher resolution down to scales of 50–100 km has been achieved in regionalized models that image a limited region involving continental or island arc scale models (e.g., Grand, 1987; Spakman *et al.*, 1989, 1993; Zhou and Clayton, 1990;

Spakman, 1991; van der Hilst *et al.*, 1991; van der Hilst *et al.*, 1993, 1995; Wu and Levshin, 1994; Engdahl *et al.*, 1995; Alsina *et al.*, 1996; van der Lee and Nolet, 1997). These regionalized models reveal strong small-scale heterogeneity in structure embedded within the larger provinces imaged by global inversions. There has been steady convergence in the features resolved by high-resolution global inversions and high-resolution regionalized inversions (e.g., Bijwaard *et al.*, 1999). Some of the principal characteristics of upper mantle and transition zone structure revealed by seismic tomography include the deep roots of continents, the structure of subducted slabs and surrounding mantle, and the structure of upwelling plumes.

4.5 Cratonic Roots

The inference that continents have anomalous structure extending down hundreds of kilometers (apparent in Fig. 13 and Color Plate 20), despite their large plate-tectonic motions, suggests the notion that cratonic roots are chemically and thermally stabilized over a thickness of 350 km or more, and this was labeled the tectosphere by Jordan (1975, 1988). Survival of such a deep keel over billions of years of continental drift is surprising, as there is general agreement that the thickness of continental mechanical boundary layer

FIGURE 14 Cross sections through three-dimensional tomographic P wave velocity models produced by van der Hilst *et al.* (1991, 1993) for western Pacific subduction zones. The seismic zone in the map is contoured in 100 km intervals. Faster velocity material (relative to the reference iasp91 model) is darker, with shading in 1% velocity variations. Dots are earthquake hypocenters along each of the cross sections. Mantle discontinuities at depths of 410 and 660 km are shown (from Lay, 1994).

(lithosphere) is on the order of 150–200 km thick (e.g., McNutt, 1990). Although the thermal boundary layer may be twice as thick, its deeper portions would normally be sheared and any structure ephemeral, especially for cratonic age continent, unless the deep region is stabilized by unusual chemical buoyancy or by high viscosity, perhaps as a consequence of extensive volatile depletion (e.g., Polet and Anderson, 1995). It is also possible that dynamical processes sustain anomalously cool material beneath continents as a sort of stagnant layer, but this is hard to reconcile with the complex history of motion of the continents.

Statistical analyses support the generalization that cratons have high velocity structure extending to at least 200 km depth (e.g., Wen and Anderson, 1997), but there is controversy over whether the roots extend as deep as the transition zone. Ritsema *et al.* (1998) find that the deep keel of cratons survives during active continental rifting, with the root extending to 300–350 km beneath Eastern Africa, and low-velocity zones beneath the surrounding rifts extend to 300 km or more. This favors the durability of the deep portion of the root even in the presence of active breakup. Upward deflection of the 410-km discontinuity that might be expected for colder than average mantle in the root has not been detected in some careful studies (e.g., Bostock, 1998; Li *et al.*, 1998; Flanagan and Shearer, 1998a; Fouch *et al.*, 2000). Overall, current thinking is that stable archaen and early proterozoic continental crust has an upper mantle root 200–350 km thick; this is a principal feature of the near-surface boundary layer that would not have been recognized without seismic imaging.

4.6 Slabs

Aside from localized regions of partial melting in upwellings, the strongest velocity heterogeneities in the mantle are those associated with subducted oceanic lithosphere. Seismic imaging of descending slabs has involved a great variety of studies (for extensive reviews see Lay, 1994, 1996), many of which have characterized the geometry and magnitude of the velocity heterogeneity of the slab. The velocity anomaly of the slab results from three factors. (1) The relatively low temperature of the slab (with as much as a 1000°C contrast relative to surrounding ambient mantle) intrinsically produces 3–10% high *P*- and *S*-velocity slab signatures. (2) The chemical differentiation and hydration that the oceanic lithosphere has undergone combine with the thermal anomaly to produce distinct phase equilibria in the slab material relative to ambient mantle, which can locally produce 5–6% *P*- and *S*-velocity anomalies, including elevation and depression of transition zone phase boundaries. (3) The subduction process perturbs the local mantle conditions by shear heating, induced flow, and lowering of the melting temperature in the overlying wedge as a result of volatile enrichment caused by hydrous phases extruded from the slab; this can induce partial melting

and 5–10% slow *P*- and *S*-velocity anomalies. The purpose of seismic imaging of mantle slabs is thus to study the thermal, chemical, and dynamical structure of subduction.

Seismicity extends as deep as 700 km for rapidly descending slabs (e.g., Wadati, 1935; Isacks *et al.*, 1968; Stark and Frohlich, 1985), and it is believed that all earthquakes below depths of about 100 km must take place in the relatively low temperature environment within subducted material. Pore-fluid assisted brittle failure or frictional sliding are probably responsible for most earthquakes down to depths of 300 km or so, but it is controversial whether there are any free fluids available at greater depths (perhaps as a result of breakdown of hydrous phases), so various other mechanisms have been invoked to account for earthquakes from 400 to 700 km depth. Instabilities associated with transition zone phase transformations are an extensively discussed possibility (e.g., Green and Burnley, 1989; Green *et al.*, 1991; Kirby *et al.*, 1991, 1996; Green and Houston, 1995). Both the distribution of the seismicity and the inferred strain orientations of the Earthquakes have long-been used as direct constraints on the configuration of seismically active deep slab material, the stress orientations in the slab, and the minimum depth of penetration of the downwelling (e.g., Oliver and Isacks, 1967; Isacks *et al.*, 1968; Isacks and Molnar, 1971; Vassiliou, 1984; Apperson and Frohlich, 1987; Burbach and Frohlich, 1986; Fukao *et al.*, 1987, Chiu *et al.*, 1991).

The cessation of earthquake occurrence at a given depth is not a clear guide as to the fate of the deep slab. Seismicity may terminate due to heating to a critical cut-off temperature for seismicity (e.g., Isacks *et al.*, 1968; Vlaar and Wortel, 1976; Molnar *et al.*, 1979; Wortel, 1982; Brodholt and Stein, 1988; Wortel and Vlaar, 1988), completion of the transition to fine-grained spinel which reduces the strength of the slab (Castle and Creager, 1998a), or, for material that penetrates below 660 km depth, due to the lack of instability for the perovskite phase transformation (e.g., Green and Zhou, 1996). It is known from the history of plate tectonics that far more subducted slab material must be present in the mantle than is illuminated by the current distribution of seismicity, and this material is in varying states of thermal and chemical reassimilation into the mantle (e.g., Richards and Engebretson, 1992; Lithgow-Bertelloni and Richards, 1998). The fate of the vast quantities of aseismic slab material is of central importance to models of chemical, thermal, and dynamical evolution of the planet (e.g., Silver *et al.*, 1988; Jordan *et al.*, 1989; Olson *et al.*, 1990; Lay, 1996). Although it is apparent from both their strain state and geometry that many slabs encounter increasing resistance to descent as they approach 660 km depth, this does not preclude slabs from penetrating into the lower mantle. The endothermic disassociative transformation of spinel-structured $(\text{Mg, Fe})_2\text{SiO}_4$ into perovskite-structured $(\text{Mg, Fe})\text{SiO}_3$ and $(\text{Mg, Fe})\text{O}$ near 660 km depth has a negative Clapeyron slope of -2.8 to -4.0 MPaK^{-1} (e.g., Ito and Takahashi, 1989; Ito *et al.*, 1990), which should resist slab penetration, and this

is a likely source of resistance to subduction that causes down-dip compression for almost all transition zone earthquakes. The geometry and intrinsic thermal/density anomaly of the slab near 660 km depth will determine whether the resistance from this phase transformation is sufficient to confine the slab to the transition zone or whether the slab components may simply transform to perovskite and penetrate deeper. However, even should the phase transformation be transited, there may also be viscosity increases or chemical contrasts with density increases that further prevent the slab from penetrating deeply into the lower mantle. Imaging of the seismic heterogeneity in the mantle holds the key to determining the fate of subducted slab material.

The anomalous seismic wave transmission properties of slabs were first manifested in anomalous patterns of seismic intensities for deep events across Japan dating back to 1918, but Utsu (1967) and Oliver and Isacks (1967) were the first to clearly articulate the notion that dipping seismogenic zones beneath island arcs involve regions of low seismic attenuation and high seismic wave velocity. This observation prompted a vast number of investigations of relative arrival time patterns, relative seismic amplitude and frequency content patterns, and secondary phase observations that constrained gross aspects of slabs and the surrounding mantle near subduction zones (see review by Lay, 1996, and Chapter 42 by Utsu). From these foundations developed the current approaches to imaging slab structures, which involve arrival time tomography, residual sphere modeling using *a priori* slab structures, and analysis of conversions, diffractions, and defocusing effects (Lay, 1996).

Beginning with the work of Hirahara (1977), large-scale 3D models have been developed for all major subduction zones in both regionalized and global tomographic inversions. Images like those in Figure 14 are typical of current inversions that use massive data sets of arrival times from regional and teleseismic observations (e.g., Zhou and Clayton, 1990; Spakman *et al.*, 1993; van der Hilst *et al.*, 1991, 1993; Engdahl *et al.*, 1995; van der Hilst, 1995; Zhao *et al.*, 1995; Widiyantoro and van der Hilst, 1996; and many more references in Lay, 1996). Because the coverage provided by seismic rays is very nonuniform, and because there is structural information lost in the source location process, these models are blurred images of the real structures, and there are many artifacts in the models. Nonetheless, regions of high seismic velocity are found to surround the deep seismicity, and it is accepted that the primary feature being imaged is subducted oceanic slab. In order to better recover the slab velocity structure, *a priori* slab models may be incorporated into the model formulation, leading to improved resolution of the wedge structure (Zhao *et al.*, 1995). Deal *et al.* (1999) and Deal and Nolet (1999) find that many deep artifacts in larger-scale models can also be removed when *a priori* information about the slab is incorporated into the inversion. This is critical to establishing the depth of slab penetration, for teleseismic

raypaths tend to have downward smearing of velocity anomalies. A common tendency is for the velocity anomalies of any possible lower mantle extension of slabs to be significantly reduced relative to the slab anomaly in the transition zone. This actually makes detecting the slab structure much harder.

Global inversions with high-resolution parametrizations in the vicinity of slabs also recover slab images (e.g., Inoue *et al.*, 1990; Fukao *et al.*, 1992; Vasco *et al.*, 1995; Zhou, 1996; van der Hilst *et al.*, 1997; Grand *et al.*, 1997; Bijwaard *et al.*, 1998), and the slab-related features are often consistent with those imaged by regional models. The resulting images do not have a simple end-member behavior for deep slabs. Deep slabs may flatten in the transition zone, as they do underneath the western Mediterranean, the Banda arc, the Solomon Islands, and the Izu-Bonin trench. Beneath Java and the Marianas there appear to be high velocity tabular extensions into the lower mantle, and there may be flattening followed by penetration under the Kuriles and Tonga. In some cases the features imaged in the high resolution tomography appear to connect up to lower mantle features found in lower resolution tomography, as discussed in the next section. The general consensus at this time based on tomographic imaging is that at least some slab material does appear to penetrate deeply into the lower mantle. The complexity of slab structures in the transition zone does appear to reflect the difficulty of penetrating the 660 km discontinuity, and this may be influenced by the slab dip, slab age, extent of trench roll-back, and ambient mantle flow patterns.

Although tomography has proved to be a powerful technique for resolving aspects of slab structure, it appears that increased use of *a priori* constraints in the inversions is required for suppressing artifacts. An alternate strategy for slab imaging that explicitly involves assumption of a slab structure is the residual sphere modeling approach. Residual spheres are simply focal sphere projections of arrival time anomalies at positions corresponding to their raypath azimuths and take-off angles from the source, and such plots have long been used to characterize patterns in seismic data (e.g., Davies and McKenzie, 1969; McKenzie and Julian, 1971; Toksöz *et al.*, 1971; and many other references in Lay, 1996). Observed arrival-time anomalies are strongly affected by the process of locating the event, which removes degree 0 and degree 1 patterns from the observations, and it is important to account for this in the modeling. To further isolate the near-source contributions to the arrival-time patterns, corrections for propagation effects outside the slab (deep mantle and near receiver) must be made, and typically some smoothing is applied to suppress random error. For a specified source location in a slab structure 3D raytracing or numerical methods are used to predict the arrival time at each station, and the model times are processed by an event location filter and any smoothing, with slab model parameters being perturbed to match the data.

Jordan (1977) initiated the complete residual sphere modeling formalism, which was further developed by Creager and Jordan (1984, 1986). These studies demonstrated the sensitivity of the method to both upper mantle and transition zone slab geometry and velocity heterogeneity, as well as to geometry of any steeply dipping slab extension into the lower mantle. Provocative results based on both *P* and *S* wave modeling suggested that slab penetration to depths of at least 1000 km with little distortion other than steepening dip occurs in the Kurile, Marianas, and Japan arcs. Additional applications of the method were presented by Fischer *et al.* (1988, 1989), Zhou and Anderson (1989), Zhou *et al.* (1990), Boyd and Creager (1991), Ding and Grand (1992) and Pankow and Lay (1999). The method makes very explicit the limitations of arrival-time data, as event location effects have a huge effect on relative arrival-time anomalies if the data coverage is limited (particularly true if only teleseismic observations are used). Tomographic methods will be strongly biased by this unless the data coverage is such that residual patterns faithfully preserve the slab effects (which may be true when extensive upgoing and downgoing data are included, but not otherwise). Residual sphere modeling also makes clear the importance of deep mantle and receiver corrections, and early applications did not adequately address this issue. In fact, it has been shown that for *S* waves much of what was initially attributed to near-source effect is eliminated when improved path corrections are applied (e.g., Schwartz *et al.*, 1991; Gaherty *et al.*, 1991; Pankow and Lay, 1999). As global tomographic models improve, this will become less of a problem. Analysis of differential residual spheres for events in the same slab, as first introduced by Toksöz *et al.* (1971) is one approach that has been pursued to suppress distant effects rather completely (e.g., Takei and Suetsugu, 1989; Okano and Suetsugu, 1992; Ding and Grand, 1992; Pankow and Lay, 1999). These studies indicate that in some cases slabs may penetrate to depths of 800 km or more, but significant slab broadening may occur, as well as reduction of velocity heterogeneity to on the order of 2%, much weaker than in early residual sphere studies, and similar to the weak heterogeneity inferred when *a priori* slab structures are introduced into tomographic modeling.

In addition to arrival time imaging, the velocity gradients and internal structure of subducting slabs have been extensively investigated using waveform conversions, diffractions and defocusing effects (see Lay, 1996 for a review). Conversions of *P*-to-*S* and *S*-to-*P* energy have been used to constrain the velocity contrasts, dip, and sharpness of slab features in many studies since about 1953 (e.g., Katsumata, 1953; Okada, 1971; Nakanishi *et al.*, 1981; Matsuzawa *et al.*, 1990; Helffrich and Stein, 1993; and many other references in Lay, 1996). Such observations are used to explore the detailed structure of the layered slab, with evidence for both high- and low-velocity layers near the top of the slab (possibly involving the eclogitic crust) and the existence of velocity

contrasts within the slab that may be associated with double layers of seismicity detected in many regions. Imaging internal slab structure is also of interest for detecting the position of phase boundaries in the slab (key temperature indicators) as well as possible metastable depression of such boundaries (e.g., Solomon and U, 1975; Roecker, 1985; Iidaka and Suetsugu, 1992; Collier and Helffrich, 1997; Koper *et al.*, 1998; Flannagan and Shearer, 1998b). As indicated earlier, there are conflicting results on the nature of major phase-boundary deflections inside the slab, and a thin wedge of metastable olivine has not been resolved. Diffraction and defocusing effects have been used to bound slab velocity gradients in many studies (e.g., Sleep, 1973; Cormier, 1989; Weber, 1990; Sekiguchi, 1992; Silver and Chan, 1986; Vidale, 1987; Gaherty *et al.*, 1991; Vidale *et al.*, 1991), but computational limitations and the difficulties of accounting for wave-propagation effects on amplitudes and waveforms have limited the contribution of such studies.

4.7 Upwellings and Plumes

Seismic methods intrinsically image downwelling high-velocity structures like slabs better than hot, upwelling low-velocity structures for two reasons: slabs often have deep focus earthquake sources in the cold downwelling that provide improved raypath coverage of the surrounding structures, whereas hot upwellings tend to have only shallow activity; and wave propagation through hot, low seismic velocity regions involves significant wave front healing, attenuation, and diffraction effects that obscure the travel-time signature. Nonetheless, regions of expected upwelling beneath major volcanic centers have been the target of many tomographic investigations, for the purpose of ascertaining the size and geometry of the zone of partial melting. Crustal structures beneath volcanic centers are described in Chapter 25 by McNutt and Chapter 26 by Benz *et al.*, and only mantle features are considered here.

Global tomography provides limited resolution of presumed upwelling regions at this point, in part due to the spatially localized nature of most upwellings. The best-imaged regions are the large-scale features associated with the mid-ocean ridge system. Surface wave and long-period body wave tomography indicate that low velocity material underlies almost all of the midocean ridge system on scale-lengths that can be resolved even in models with only 1000 km scale resolution (e.g., Zhang and Tanimoto, 1991; Su and Dziewonski, 1997; Trampert and Woodhouse, 1996; Ekström *et al.*, 1997; Boschi and Dziewonski, 1999; Ritsema *et al.*, 1999). The depth extent of the low-velocity region under ridges is less-well resolved, with some studies indicating concentration of low-velocity material in the upper 100 km (e.g., Zhang and Tanimoto, 1991, 1992), but the more compelling case being that low-velocity material extends down to at least 250 km below fast-spreading ridges such as the Pacific

rise (e.g., Su *et al.*, 1992; Su and Dziewonski, 1997). Global *P*-wave tomography models typically have poor sampling of midocean ridge systems, and little vertical resolution of upper mantle structure, in contrast to their resolution of downwellings. The lack of nearby stations causes strong trade-offs between mantle structure and source parameters for near-ridge events. The existence of low velocity material at depths down to 400 km beneath ridges is strongly supported by body-wave analysis of *SS*, *SSS* and *SSSS* phases (e.g., Graves and Helmberger, 1988; Grand *et al.*, 1997). However, transition zone discontinuities beneath the Pacific rise do not appear to have anomalous depths as might be expected if thermal anomalies extend through to the lower mantle (e.g., Shen *et al.*, 1998; Lee and Grand, 1996). The prevailing notion is that most midocean ridge upwellings are relatively passive in nature, with partial melting occurring as a result of pressure reduction as material rises super-adiabatically into the ridge.

Acute heterogeneity and concentrations of low-velocity upwellings are imaged in the upper mantle wedge above subducting slabs, with the best detail being provided by regional-scale tomographic inversions (e.g., Zhao *et al.*, 1992, 1994, 1995, 1997). The low velocity regions are so pronounced that they likely involve significant partial melting, which is thought to be the result of lowering of the melting temperature due to the presence of volatiles released from the subducting slab. Upwellings are also inferred from low-velocity structure found below continental rift zones such as the East African rift. These appear to extend deep into the upper mantle as well, with low velocity *P* and *S* anomalies as deep as 350 km (e.g., Su and Dziewonski, 1997; Ritsema *et al.*, 1998). Deep structures that may correspond to frozen-in plume features have also been imaged by tomography under South America (Van Decar *et al.*, 1995).

There has also been great interest in studying the structure under major hotspots such as Iceland, Yellowstone, and Hawaii. Global surface wave tomography has not resolved the 100–200 scale structures of relevance, but there is some suggestion that many large hotspots are underlain by low-velocity material in the upper 200 km of the mantle (Zhang and Tanimoto, 1991). Tomographic inversion of *P*-wave arrival anomalies suggests that low velocities extend to at least 400 km depths below Iceland as a large cylindrical structure with a radius of about 150 km (Tryggvason *et al.*, 1983; Wolfe *et al.*, 1997). Shear-wave anomalies in this structure are as large as -4% whereas *P*-wave anomalies are -2% . This requires temperature anomalies of on the order of 200–300°C. Shen *et al.* (1998) examine topography of the 410 and 660-km discontinuities beneath Iceland as indicated by *Pds* conversions in receiver functions, and find that the transition zone is about 20 km thinner than average, which they interpret as evidence for a lower mantle origin of the thermal upwelling. Similar deflections of the transition zone discontinuities are observed along the Yellowstone hotspot track (e.g., Dueker, and Sheehan, 1997), although the

primary low velocity features imaged by tomography are concentrated in the range 50–200 km beneath the Snake River Plain (Dueker and Humphreys, 1990; Saltzer and Humphreys, 1997). Travel-time anomalies for *P* waves beneath other hotspots have been interpreted as being caused by plumes extending through the transition zone (Nataf and VanDecar, 1993).

4.8 Laterally Varying Anisotropy

The average upper mantle velocity structure can be characterized as transversely isotropic, as described above. A model like PREM provides a first-order fit to global Love and Rayleigh wave dispersion observations, as well as equivalent toroidal and spheroidal eigenfrequencies. However, the very nature of anisotropy, involving large-scale alignments of intrinsically anisotropic minerals such as olivine, systems of oriented cracks, or sheared fabrics or lamellae, is such that lateral variations in anisotropic properties are expected throughout the crust and upper mantle. This is actually found to be the case, with lateral variations in the anisotropic structure of the lithosphere and asthenosphere for both continental and oceanic regions having been imaged by a variety of body-wave and surface-wave methods.

Global and plate-scale tomographic inversions of surface wave dispersion measurements have incorporated anisotropic structure either in the reference model (by using PREM), or explicitly in the parameterization of the model (e.g., Nataf *et al.*, 1984, 1986; Nishimura and Forsyth, 1989; Montagner and Tanimoto, 1990, 1991; Ekström and Dziewonski, 1998). Ekström and Dziewonski (1998) demonstrate convincingly that the contributions to surface-wave travel times from anisotropy variations are significant, and allowance for spatial variations in anisotropy is both justified and necessary. Ekström and Dziewonski (1998) find that the radially varying transverse isotropy of PREM is a good average model for both oceanic and continental regions, even when there are substantial baseline shifts in the average velocities. The main exception is the central Pacific plate where there are strong geographical variations in radial anisotropy, with maximum anisotropy differences being much stronger than in PREM around 150 km deep. It appears that actual anisotropy in the Pacific plate is not simply transverse isotropy, but azimuthal anisotropy (which causes wave speed to vary with azimuth, not just polarization), but mapping of azimuthal anisotropy is still rather poorly constrained (e.g., Nishimura and Forsyth, 1988, 1989; Montagner and Tanimoto, 1991; Ekström and Dziewonski, 1988). As constraints on the geometry and variations in anisotropy improve, it will be possible to relate the anisotropic observations to models of shear flow that induce lattice preferred orientations (LPO) or fabrics in the upper mantle lithosphere and asthenosphere (e.g., Tanimoto and Anderson, 1984; Montagner, 1994).

Continental observations of seismic anisotropy have primarily involved body-wave measurements of shear-wave splitting and azimuthal Pn travel times, although surface-wave observations in the continents do support the existence of upper mantle anisotropy (e.g., Gaherty *et al.*, 1996). Silver (1996) and Savage (1999) review the observations of upper mantle anisotropy and the basic hypotheses for interpreting anisotropy as a result of either frozen or actively supported fabrics in the rocks. The most extensively analyzed phases have been SKS phases, which traverse the core as a P phase, and hence have a known initial polarization at the core–mantle boundary on their path to the surface. Vinnik *et al.* (1984, 1989, 1992), Kind *et al.* (1985) and Silver and Chan (1988, 1991) established methods for analyzing the splitting of SKS signals to determine the orientation and magnitude of azimuthal anisotropy, typically under the assumption of a horizontal symmetry axis for hexagonal crystals. A large number of analyses of S and SKS splitting to determine receiver and source-side anisotropic structure have ensued (see Savage, 1999 for many references), demonstrating that the Earth's lithosphere has extensive azimuthal anisotropy, sometimes with large-scale coherence, and sometimes with small-scale regional variations. The rapid variations that are sometimes observed require that the anisotropy be concentrated in the shallow mantle, but the magnitude of splitting (values as large as 2–3 sec have been observed) requires that the anisotropy be as strong as 2.5–3% over the upper 250 km of the mantle. Analysis of splitting for earthquakes at different depths suggest anisotropy of 0.5–2% for the mantle above and below slabs and up to 5% within slabs (e.g., Shih *et al.*, 1991; Kaneshima and Silver, 1995; Fouch and Fischer, 1996; Hiramatsu *et al.*, 1997). Splitting generally does not increase with source depth for events deeper than 400 km (e.g., Kaneshima and Silver, 1995; Fouch and Fischer, 1996; Fischer and Wiens, 1996), however, there is limited evidence for transition zone anisotropy in converted phases (Vinnik and Kind, 1993; Vinnik and Montagner, 1996) and from modeling body-wave and normal-mode observations (Montagner and Kennett, 1996). As yet, there is not a fully satisfying reconciliation of the global model of transverse isotropy provided by PREM and the extensive observations of laterally varying azimuthal anisotropy provided by body-wave studies. It appears that the mantle requires a more general parameterization than transverse isotropy, but the data feeding into global tomographic inversions and reference Earth models are not yet sufficient to constrain the complete anisotropic orientation.

4.9 Attenuation

The foregoing discussion has emphasized elastic properties of the crust and mantle, primarily constrained by elastic wave travel times. However, the Earth is not perfectly elastic, and seismic waves of all types undergo anelastic attenuation as

they propagate. This results in amplitude decay at a rate exceeding that caused by geometric spreading, along with slight dependence of seismic velocity on frequency, or dispersion. In general, the mechanisms that cause anelastic losses are thermally activated microscale processes such as dislocation motions and grain boundary interactions (see Anderson, 1967b; Minster, 1980; Minster and Anderson, 1981). One of the primary goals of studying attenuation is to constrain thermal structure inside the planet. The details of microscale processes that cause attenuation are not resolvable with seismic waves, which intrinsically average large volumes, so phenomenological models are used to account for the macroscopic effects of anelasticity (see Lay and Wallace, 1995). The most common parametrization is in the form of the quality factor, Q , defined as the inverse of the fractional loss of energy, E , per cycle of oscillation: $1/Q = -\Delta E/2\pi E$. As Q increases, the attenuation is smaller, and for infinite Q , the elastic solutions are retrieved. Attenuation quality factors can be defined for all types of seismic waves, with the corresponding value depending on the specific path through the Earth, the sense of particle motion involved in the wave, and the frequency of the vibration. Suitably designed experiments have allowed Q values to be estimated for body waves and surface waves for more than four decades (e.g., Sato, 1958; Bath and Lopez, 1962; Anderson, 1963; Press, 1964; Anderson and Archambeau, 1964; Anderson and Kovach, 1964; Ben-Menahem, 1965). Generally, P -wave quality factors (Q_α) are higher than S -wave quality factors (Q_β) (see Fig. 3), and it is believed that most intrinsic attenuation is related to shear processes associated with lattice defects and grain boundaries (for a Poisson solid with all losses due to shearing mechanisms, $Q_\alpha = 9/4 Q_\beta$) (e.g., Anderson *et al.*, 1965). Observationally, Q for seismic waves in the mantle is not strongly dependent on frequency over the band 0.001–0.2 Hz, with typical Q_β values of 100–500 or so, but at higher frequency the attenuation is lower, and Q increases with frequency.

The existence of attenuation modifies the equations of motion for Earth materials from those for pure linear elasticity. However, for the moderate Q values found in the Earth, good approximations of the solution for the full viscoelastic equations can be obtained by perturbation of the elastic solutions with effective attenuation operators (see Lay and Wallace, 1995). For example, the amplitude spectrum for a propagating P or S wave is modified by a term like: $A(f) = A_0 e^{(-\pi f t^*)}$, where

$$t^*(f) = \int_s \frac{ds}{v(s)Q(s,f)} \quad (3)$$

with s being a variable along the path, $v(s)$ being the velocity encountered on the path, and $Q(s,f)$ being the spatially and frequency varying attenuation factor. The finite Q encountered by a seismic wave, even if it is approximately constant over

a frequency band, results in frequency dependence of seismic wave velocity, with higher frequencies sensing an unrelaxed effective modulus and having higher velocities than lower frequencies, which sense a relaxed effective modulus (e.g., Futterman, 1962; Jeffreys, 1965; Liu *et al.*, 1976; Kanamori and Anderson, 1977; Anderson *et al.*, 1976). The frequency dependence of physical mechanisms that cause attenuation is usually treated using the standard linear solid model, for which each physical mechanism influences a characteristic frequency band defined by a Debye peak, and a propagating wave encounters a distribution of distinct mechanisms that superimpose to produce an effective absorption band over a range of frequencies. The systematic variation of elastic velocities with frequency is observed in the Earth, and must be accounted for in order to reconcile Earth models based on short-period body waves with those based on long-period normal modes (e.g., Hart *et al.*, 1977; Montagner and Kennett, 1996). The PREM model, which has a radially varying constant Q structure, thus has explicitly frequency dependent seismic velocities (Dziewonski and Anderson, 1981).

There have been extensive measurements of attenuation for globally sampling data sets of surface waves and free oscillations (e.g., Kanamori, 1970; Anderson and Hart, 1978; Sailor and Dziewonski, 1978; Nakanishi, 1979; Dziewonski and Anderson, 1981; Masters and Gilbert, 1983; Smith and Masters, 1989; Roult *et al.*, 1990; Romanowicz, 1990; Widmer *et al.*, 1991; Durek *et al.*, 1993; Romanowicz, 1995; Durek and Ekström, 1996). Average Q_β models for the upper mantle are shown in Figure 15. The lithosphere is relatively high Q , but there are Q_β values of 60–70 in the vicinity of the low velocity zone, which suggests a connection between partial melting and strong attenuation. The Q of the lower mantle is much higher (Fig. 3), thus most attenuation is believed to take place along the upper mantle portion of wave paths. The more recent of the global studies have produced

FIGURE 15 Spherically averaged Q models for the upper mantle from various studies of surface wave and normal mode attenuation (from Romanowicz, 1995).

low resolution (up to degree 6) tomographic models of aspherical attenuation that show a negative correlation with models of shear velocity variations as would be expected for temperature effects (e.g. Durek *et al.*, 1993; Romanowicz, 1995). Relatively low Q values are found in the upper mantle under the Pacific and under Eastern Africa. In general, there are higher Q regions underlying most continental areas than underlying oceanic regions (e.g., Dziewonski and Steim, 1983; Romanowicz, 1995). The lateral variations in attenuation are particularly important to account for when inferring thermal anomalies from seismic tomography, because the dispersive effect in low Q regions, which tend to be hot and low seismic velocity, accentuates the velocity anomaly for a given thermal heterogeneity (e.g. Karato, 1993). The tomographic inversions for attenuation are complicated by the need for correcting for focusing and defocusing effects of velocity heterogeneity, and it is likely that joint inversions for velocity structure and attenuation structure will be pursued in the future.

Higher spatial resolution measurements of attenuation for body and surface waves indicate that Q varies laterally by an order of magnitude, especially in the upper mantle. This means that the average radial Q model for PREM, which has an average value of $Q_\beta = 128$ in the upper 400 km of the mantle, is only useful for normal modes and long-path surface waves, which involve extensive lateral averaging. For body waves in the period range 30–1 sec, average values of t^* are 1 ± 0.5 sec for P waves and 4 ± 2 sec for S waves, whereas at shorter periods of 1–0.1 sec the t^* values may decrease to 0.1 or 0.2 sec on specific paths (e.g., Sipkin and Jordan, 1980; Der *et al.*, 1980; Taylor *et al.*, 1986; Chan and Der, 1989; Flanagan and Wiens, 1990; Sheehan and Solomon, 1992; Ding and Grand, 1993; Bhattacharyya *et al.*, 1996; and many more). The exponential form of the t^* operator still means that high frequencies are strongly attenuated on paths through the mantle. The lateral variations in attenuation beneath continental areas have been of particular importance for nuclear explosion monitoring, with estimates of explosion yields trading off directly with estimates of the seismic attenuation of the high frequency P waves from explosions. This has prompted extensive work on the variation and frequency dependence of attenuation for periods near 1 sec (see discussions by Bache, 1985; Burger *et al.*, 1987). Overall, models for attenuation in the mantle remain relatively primitive, but first-order mapping of the structure has been achieved.

5. Lower Mantle

The lower mantle extends from 800 to 2890 km deep, where the Earth's primary internal compositional contrast exists at the core–mantle boundary. For most of this depth range, the structure appears to be relatively uniform, free of major radially symmetric boundaries, and quite plausibly composed of uniform composition of $(\text{Mg}_{0.9} \text{Fe}_{0.1})\text{SiO}_3$ perovskite, with

FIGURE 16 Variation of seismic velocities and density through the lower mantle for model PREM, along with extremal bounds that indicate the confidence interval for spherically averaged models based on travel-time data. The D'' region is the lowermost 200 km of the lower mantle overlying the core-mantle boundary (CMB) (from Lay, 1989).

(Mg, Fe)O and minor additional components such as SiO₂-stishovite and calcium perovskite. No major phase changes in these primary components are expected over the pressure range of the lower mantle. Seismic velocity models for the lower mantle (Fig. 16) differ very little from the classical models of Gutenberg and Jeffreys except near the 660 km discontinuity and at the base of the mantle, largely because the travel-time curves for *P* and *S* waves are remarkably free of complexity in the range of 30–100 degrees and therefore provide tight constraints on the structure (Fig. 1). Nonetheless, there have been substantial contributions to our understanding of mantle dynamics and chemical evolution as a result of detailed studies of lower mantle structure, and vigorous research is being pursued to map out small aspherical structures as well as detailed structure of the base of the transition zone and in the lowermost 200 km of the lower mantle, which Bullen (1949) identified as an inhomogeneous zone and labeled the D'' region.

5.1 Radially Symmetric Structure/Discontinuities

The average lower-mantle properties have been determined by both classical arrival time inversion and by normal mode analysis, with the latter refining early estimates of the density structure that had been based on velocity-density systematics, integral constraints on Earth's mass and moment of inertia, and integration of seismic velocity models using the Adams-Williamson equation (Adams and Williamson, 1923). Global observations of body wave travel times, measurements of slopes of the travel-time curves by seismic array analyses, and

measurements of normal-mode eigenfrequencies proliferated in the 1960s to 1980s, with many radially symmetric Earth models for the lower mantle being produced (e.g., Chinnery and Toksöz, 1967; Hales *et al.*, 1968; Herrin, 1968; Johnson, 1969; Hales and Roberts, 1970; Randall, 1971; Jordan and Anderson, 1974; Gilbert and Dziewonski, 1975; Dziewonski *et al.*, 1975; Sengupta and Julian, 1978; Uhrhammer, 1978; Dziewonski and Anderson, 1981; Kennett and Engdahl, 1991; Morelli and Dziewonski, 1993). Although the lower mantle variations among these models are less than 1%, there is still great importance in having an accurate reference model both for earthquake location procedures and for use as a background model in tomographic analyses (reference model structures are often optimized in the very process of producing a tomographic model). Thus, efforts to improve the average lower mantle parameters continue, with increasing quantities of data and variety of phase types being incorporated into the analysis (Masters *et al.*, 1999). All of these average lower mantle models have smooth velocity gradients with no significant structures other than reductions of velocity gradients in the D'' region, as in the PREM model (Fig. 16).

The small variations between lower mantle radial velocity models have still received much attention because any departure from homogeneity (as expected for self-compression of uniform composition material) would have major implications for possible chemical layering or phase changes. *P* and *S* velocities throughout the lower mantle above the D'' region are bounded to within about $\pm 0.1 \text{ km sec}^{-1}$ in terms of an average model (e.g., Lee and Johnson, 1984). This tight bound (Fig. 16) is consistent with the finding by Burdick and Powell (1980), that small features in ray parameter estimates from seismic arrays tend to vary azimuthally, and are not globally representative, with on average very smooth structure in the lower mantle being preferred as an average model. There have been observations of reflections and converted phases from a velocity or impedance contrast near 900 km depth near subduction zones (e.g., Revenaugh and Jordan, 1991; Kawakatsu and Niu, 1994), but this appears to be a strongly laterally varying structure (Shearer, 1993), and may be associated with steeply dipping mantle heterogeneities (Niu and Kawakatsu, 1997; Kaneshima and Helffrich, 1998; Vinnik *et al.*, 1998; Castle and Creager, 1999). At this time there is no compelling evidence for significant laterally extensive layering of the lower mantle except near the top of the D'' region.

The lower mantle has relatively high *Q* values for seismic waves (see Fig. 3), and mapping any lateral variations is very difficult due to the strong regional variations in the upper mantle. Normal modes and averaged body-wave attenuation measurements place some constraints on the average *Q* values, but it is possible to satisfy most data with extremely simple models (e.g., Dziewonski and Anderson, 1981; Masters and Gilbert, 1983). Although there is some evidence for a low *Q* zone at the base of the mantle, this is not well

resolved because of strong trade-offs with velocity gradients in the D'' region.

5.2 D''

The existence of the Earth's magnetic field, caused by ongoing thermochemical convection and an associated geodynamo in the conducting iron alloy core, requires that heat is fluxing from the core into the mantle. While estimates of the total heat budget of the mantle indicate that heating from below comprises only 10–30% of the total mantle heat flux (the balance is from residual internal heat and radioactive decay in the mantle), a thermal boundary layer should exist at the base of the mantle, with a rapid increase in temperature across a conductive boundary layer. Like the Earth's other major thermal boundary layer in the lithosphere, the boundary layer at the base of the mantle is likely to be undergoing strong lateral and vertical flow, as upwellings produced by thermal boundary layer instabilities drain hot material from the boundary layer and downwellings replace it with cooler material. As a hot, low viscosity boundary layer, it is likely that there is much more small-scale structure in the dynamical regime than is found in the relatively stiff lithosphere. It is generally accepted that heterogeneity within the thermal boundary layer is partially responsible for the inhomogeneity detected by Dahm (1934) and confirmed by Bullen (1949) as well as for the reduced seismic velocity gradients in the region found in some of the average Earth models (e.g., Stacey and Loper, 1983; Lay and Helmberger, 1983; Doorbos *et al.*, 1986; Loper and Lay, 1995). However, the juxtaposition of the boundary layer adjacent to the largest density contrast in the Earth (the density jump across the core–mantle boundary is larger than that at the surface of the Earth) heightens the probability that there is also chemical heterogeneity in the D'' region, caused by either density-stratified residue from the Earth's core formation process, ongoing chemical differentiation of the mantle, or even chemical reactions between the core and mantle (e.g., Lay, 1989; Knittle and Jeanloz, 1989; Goarant *et al.*, 1992; Jeanloz, 1993; Manga and Jeanloz, 1996). Because of its importance for unraveling the thermal and chemical processes in the mantle many seismological studies have characterized the structure of the D'' region (see the survey papers in Gurnis *et al.*, 1998, and reviews by Loper and Lay, 1995; Weber *et al.*, 1996; Lay *et al.*, 1998; Garnero, 2000).

The existence of the great velocity reductions across the core–mantle boundary (CMB) causes seismic wave energy to diffract into the geometric shadow zone at distances greater than 100°. Waves diffracted along the core are sensitive to the absolute velocities and the velocity gradients in the D'' region, and have long been studied to constrain average and laterally varying structure (e.g., Alexander and Phinney, 1966; Sacks, 1966; Bolt *et al.*, 1970; Mondt, 1977; Doorbos and Mondt, 1979; Mula and Müller, 1980; Wyssession and Okal, 1989; Wyssession *et al.*, 1992; Valenzuela and Wyssession, 1998, and

many more). These studies demonstrate that no single velocity structure sufficiently characterizes D'' everywhere, and that in some cases there are strong negative velocity gradients in D'' while in other places there are near-zero or positive velocity gradients. There are also changes in the relative perturbation of *P* and *S* velocities that are likely due to mineralogical or textural origin (e.g., Wyssession *et al.*, 1999). These phases involve extensive lateral averaging of what appears to be a region rich in small-scale structure, but they provide important input into large-scale tomographic models for D'' because of their extensive spatial coverage (e.g., Kuo and Wu, 1997; Kuo *et al.*, 2000; Castle *et al.*, 2000).

Both *P*- and *S*-velocity structure have velocity discontinuities, or zones of rapid velocity increase over depth ranges of no more than 30–50 km, at many locations near the top of the D'' region (the top of D'' is not precisely defined, and many take it to correspond to either where there is a discontinuity or the onset of a change in velocity gradient, which may be from 50 to 350 km above the CMB). The velocity increases are detected by reflections and triplications, which arrive ahead of the core-reflected *PcP* and *ScS* phases (e.g., Wright and Lyons, 1975; Lay and Helmberger, 1983; Wright *et al.*, 1985; Young and Lay, 1987, 1990; Gaherty and Lay, 1992; Weber and Davis, 1990; Houard and Nataf, 1993; Weber, 1993; Kendall and Shearer, 1994; Kendall and Nangini, 1996; Ding and Helmberger, 1997; Thomas and Weber, 1997; Kohler *et al.*, 1997; Reasoner and Revenaugh, 1999; and many others reviewed by Wyssession *et al.*, 1998). The reflector varies in depth by several hundred kilometers (e.g., Kendall and Shearer, 1994), and appears to have short wavelength lateral variations of on the order of 100 km that may produce scattering rather than simple reflections (e.g., Weber, 1993; Kruger *et al.*, 1995; Lay *et al.*, 1997; Scherbaum *et al.*, 1997; Yamada and Nakanishi, 1998; Freybourger *et al.*, 1999; Emery *et al.*, 1999). It has been argued that the discontinuities are actually globally extensive, caused by a phase change, with lateral variations in depth and strength (velocity increases vary from 1 to 3%) being the result of lateral temperature variations and interactions with upwelling and downwelling flow (e.g., Nataf and Houard, 1993; Sidorin *et al.*, 1998, 1999). Others have questioned whether there is a first-order discontinuity or simply scattering from strong velocity heterogeneities as imaged in long-wavelength tomography models (e.g., Liu *et al.*, 1998). The latter possibility requires large *ad hoc* increases in the magnitude of the tomographic heterogeneities, and does not appear to be a viable explanation for the broadband reflections that are observed. However, thin high or low velocity lamella models may fit some *P*-wave observations (Weber, 1994; Thomas *et al.*, 1998; Freybourger *et al.*, 1999). Thus, at present, the interpretation of the D'' discontinuity is uncertain, and work continues on characterizing this structure and its dynamical significance. Of particular importance will be determination of whether there is any density increase in D''

that might represent a chemical change or phase change, either of which could strongly affect the dynamics of the boundary layer (e.g., Sleep, 1988; Kellogg, 1997; Montague *et al.*, 1998; Hansen and Yuen, 1988; Tackley, 1999).

The large-scale variations in D'' imaged by seismic tomography have surprising predominant degree 2 and 3 spherical harmonic components (e.g., Su *et al.*, 1994; Li and Romanowicz, 1996; Masters *et al.*, 1996; Dziewonski *et al.*, 1996; Kuo and Wu, 1997; Liu and Dziewonski, 1998; Kuo *et al.*, 2000). These models show consistent high shear velocities rimming the Pacific plate, with low velocities beneath the central Pacific and the southeastern Atlantic and southern Africa. This geometry produces a correlation between areas of slab subduction over the past several hundred million years (e.g., Lithgow-Bertelloni and Richards, 1998) and fast regions of D'' , which could result if slabs sink to the base of the mantle and retain enough thermal anomaly to produce high seismic velocities. Similarly, the low-velocity regions of D'' are generally below hotspot regions at the surface, suggesting that D'' upwellings may penetrate all the way to the Earth's surface. This will be discussed further below.

Small-scale variations in D'' , with about 1% heterogeneities on scale-lengths of about 10 km are also present. This was first established by interpretation of short-period precursors to PKP phases (e.g., Cleary and Haddon, 1972; Haddon and Cleary, 1974; Doornbos, 1976; Bataille and Flatté, 1988; Bataille *et al.*, 1990; Hedlin *et al.*, 1997; Cormier, 1999). It has generally been believed that the levels of heterogeneity increase in D'' relative to the overlying mantle, but there is weak evidence that small-scale structure in D'' is not distinctive (e.g., Hedlin *et al.*, 1997). It is clear that some of

the strongest scattering, involving much larger velocity heterogeneities, does arise within D'' (Vidale and Hedlin, 1998; Wen and Helmberger, 1998), and this is likely associated with an intermittent thin layer of partial melt that causes an ultra-low velocity zone (ULVZ) just above the CMB. The bandwidth of the signals used in scattering analyses controls the sensitivity to scatterers of different dimensions, and analysis of broadband data indicates a rich spectrum of scattering scalelengths in D'' .

Evidence for an ULVZ at the base of the mantle was first presented by Garnero *et al.* (1993) and Silver and Bina (1993). A layer from a few to tens of kilometers thick with as much as 10% P velocity reduction and 30% S velocity reduction is found in some regions of the lower mantle (Fig. 17), with the primary evidence (see Garnero *et al.*, 1998 for a review) being delayed $SP_{diff}KS$ phases (e.g., Garnero and Helmberger, 1995, 1998; Helmberger *et al.*, 1998) and the shape of precursors to PcP reflections (e.g., Mori and Helmberger, 1995; Revenaugh and Meyer, 1997). The strong velocity reductions tend to be most easily explained by partial melting (Williams and Garnero, 1996), suggesting that some component of the mantle is exceeding its solidus at the hottest temperatures of the thermal boundary layer. There is fairly strong correlation between locations of ULVZ patches and slower than average shear velocities in D'' and the overlying lower mantle, which is suggestive of a relationship between partial melting in D'' and large-scale upwellings (e.g., Williams *et al.*, 1998). There is presently extensive effort to map and interpret the ULVZ feature, as it potentially has significant implications for chemistry and dynamics of D'' (Garnero, 1999).

FIGURE 17 Mollweide projection of Earth showing the ULVZ distribution at the base of the mantle. Light shading corresponds to the Fresnel zone regions where a ULVZ has been detected. Dark regions are where no ULVZ has been detected. No shading corresponds to no coverage. Black-filled circles are hot spot locations (where there is ULVZ coverage), scaled to buoyancy flux estimates. Crosses are location of calculated lower mantle density anomalies due to subducted material (From Garnero *et al.*, 1998).

Given the complexity of structure at all scales in D'' , it is not surprising that uncertainty remains as to whether there is any topography on the core–mantle boundary itself. Long wavelength topography of the CMB was proposed by Creager and Jordan (1986) and Morelli and Dziewonski (1987) based on studies of bulletin *PcP* and *PKP* arrival times, but it has been demonstrated that allowing for strong heterogeneity in D'' and the limited resolution of the available data make CMB topography models very uncertain (e.g., Doornbos and Hilton, 1989; Rodgers and Wahr, 1993; Pulliam and Stark, 1993; Obayashi and Fukao, 1997; Garcia and Souriau, 2000). As models for the entire mantle improve, this may prove to be a solvable problem, and it is a critical one, for it plays a major role in estimating the extent of mechanical coupling between the core and mantle. For imaging shorter-wavelength topography of the CMB, the primary approach has involved travel-time fluctuations and precursors to underside reflections of internal core reverberations (*PKKP*). These phases provide an upper bound of about 100 m topography on 10 km scale lengths (e.g., Doornbos, 1974, 1980; Chang and Cleary, 1978; Bataille and Flatté, 1988; Earle and Shearer, 1997, 1998).

Although the bulk of the lower mantle does not appear to have large-scale organized anisotropy, the D'' region has been shown to have extensive regions where shear-wave splitting occurs (see review by Lay *et al.*, 1998a, b). Observations of splitting for *ScS* phases have been made for several decades (e.g., Mitchell and Helmberger, 1973; Lay and Helmberger, 1983b), but observations of diffracted waves convincingly demonstrated that anisotropy is present in D'' (e.g., Vinnik *et al.*, 1991, 1995, 1998; Lay and Young, 1991; Kendall and Silver, 1996; Matzel *et al.*, 1996; Garnero and Lay, 1997; Ritsema *et al.*, 1998; Russell *et al.*, 1998). These observations have prompted increased consideration of the anisotropic crystallography of high pressure phases likely to be present in the lower mantle along with what deformation mechanisms are likely to control the formation of fabrics (e.g., Stixrude, 1998; Karato, 1998). At this time, there are substantial uncertainties in the nature of the anisotropy and its cause. In many places it appears that transverse isotropy with a vertical symmetry axis is consistent with the data (producing earlier *SH* arrivals than *SV* arrivals), but there are also clear observations of azimuthal anisotropy, and thus far it has only been possible to characterize the horizontal component of the symmetry axis. Strong shear flows in the boundary layer may induce lattice preferred orientation of the anisotropic lower mantle minerals, but it is not clear why this would not also hold for the overlying lower mantle. Sheared inclusions of chemical heterogeneities and pockets of partial melt may also play a role in generating the seismic anisotropy. As observational and laboratory constraints improve, it is likely that modeling anisotropy in D'' will provide an important constraint on the thermal and dynamical regime in the boundary layer.

5.3 Aspherical Lower Mantle Structure

One of the earliest fundamental contributions of global seismic tomography was the demonstration that large-scale structure exists in the lower mantle and that this unexpected configuration of deep heterogeneity can account for previously unexplained long-wavelength features in the Earth's geoid (e.g., Dziewonski *et al.*, 1977; Clayton and Comer, 1983; Dziewonski, 1984; Hager *et al.*, 1985). This required improved understanding of how mantle heterogeneities induce flow and deflection of boundaries that affect the geoid (Hager, 1984; Richards and Hager, 1984). Although the early low resolution tomographic models for the lower mantle, which have relatively strong spherical harmonic components from degrees 2 to 5, have proved remarkably successful in accounting for the long wavelength geoid (see review by Hager and Richards, 1989), there has been continuing debate about the spectrum of lower mantle heterogeneity. Are the long-wavelength patterns the result of spatial distribution of smaller scale features such as slabs embedded in the lower mantle? If so, then the long wavelength distribution of heterogeneity in the lower mantle is more a consequence of the last few hundred million years of surface tectonics than a fundamental aspect of the lower mantle. Similarly, if the long wavelength patterns in surface hotspots reflect features rising from the core–mantle boundary, then the distribution of D'' boundary layer instabilities may contribute to the present long-wavelength structure of the deep mantle. These are still open questions to a large extent, but there is significant convergence in deep-mantle tomographic shear velocity models of the current generation (e.g., Masters *et al.*, 1996; Li and Romanowicz, 1996; Grand *et al.*, 1997; Liu and Dziewonski, 1998; Ritsema *et al.*, 1999), all of which have substantial long wavelength heterogeneities. The same is true for large-scale *P* velocity models, although the level of agreement between models is not currently as strong (e.g., van der Hilst and Karason, 1999; Bijwaard and Spakman, 1999). The presence of large-scale lower-mantle features enables formulation of simultaneous or iterative inversions for dynamical features such as the geoid and dynamic topography, and this has become a new area of research (e.g., Hager *et al.*, 1985; Hager and Clayton, 1989; Dziewonski *et al.*, 1993; Phipps Morgan and Shearer, 1993; Forté *et al.*, 1993, 1994). The primary additional parameter that is constrained in such geodynamic models is the viscosity structure, and it is generally found in geoid inversions as well as contemporary studies of glacial rebound analyses that the viscosity of the lower mantle is one to two orders of magnitude higher on average than that of the average upper mantle (e.g., Mitrovica and Forté, 1997; Lambeck and Johnston, 1998).

As the resolution of lower mantle structure improves with each new generation of global tomographic model, it has become clear that there are significant intermediate scale features in the lower mantle. This had been deduced for

localized regions quite early by array studies or analyses of differential travel times for phase pairs sensitive to lower mantle structure (e.g., Jordan and Lynn, 1974; Lay, 1983), but the geometry and lateral extent of such features was not resolved until tomographic models emerged. Recent high resolution S -velocity (e.g., Grand, 1994; Grand *et al.*, 1997) and P -velocity (van der Hilst *et al.*, 1997) models resolve a high velocity tabular structure extending vertically beneath North America and South America and a similar elongate body beneath southern Eurasia, both of which extend to at least 1300–1800 km depth (Fig. 18). These are interpreted as relatively cold, sinking slab material that has penetrated into the lower mantle as the Americas moved westward and as the Tethys Sea closed, respectively. The midmantle seismic velocity near 1300 km depth is thus dominated by elongate tabular high-velocity features, and it is likely that these contribute significantly to the strong long-wavelength patterns in spherical harmonic models that have lower resolution (see corresponding features in the models discussed by Dziewonski *et al.*, 1993).

Below about 1800 km depth, tomographic models show less coherence and tabular structures are not clearly imaged (e.g., Grand *et al.*, 1997). Instead, the models become dominated by large horizontally extensive regions of high and low velocity with strong degree 2 and 3 patterns dominating in D'' , as noted above. The large-scale low-velocity regions below

the Central Pacific and Eastern Atlantic/Southern Africa do appear to extend upward above the D'' region into the lower mantle. These have been identified as “superplumes,” given that their scale greatly exceeds that expected for isolated D'' boundary layer instabilities, and Dziewonski *et al.* (1993) call them the “Equatorial Pacific Plume Group” and the “Great African Plume,” respectively. Attention has focused on large low velocity features in the lower mantle as possible deep roots of plume upwellings. Ritsema *et al.* (1998) find that velocity anomalies in the structure under southern Africa involves 3% shear velocity anomalies and strong lateral gradients, both of which are more pronounced than in the model of Grand *et al.* (1997). Even stronger anomalies are reported in the D'' region below the southeastern Atlantic, with as much as 10% S -velocity reductions in a 300 km thick layer (Wen *et al.*, 2000). Ritsema *et al.* (1999) presented a new S -velocity model in which a low velocity region extends from the core–mantle boundary under the southeastern Atlantic Ocean continuously into the upper mantle beneath eastern Africa. They do not find a low shear velocity zone in the lower mantle beneath Iceland, but Bijwaard and Spakman (1999) present a P velocity image with low velocity under Iceland all the way to the core–mantle boundary. Goes *et al.* (1999) find a low P -velocity structure beneath Europe from 660 to 2000 km depth which they invoke as the source of small plumes in the upper mantle associated with volcanism in

FIGURE 18 Horizontal section through a tomographic model of P -wave velocity structure near 1300 km in the lower mantle, obtained by inversion of ISC arrival times after careful processing for depth determination. Solid dark area correspond to high velocities, with two major coherent features that correspond to tabular structures extending vertically below southern Asia and eastern North America. These are inferred to be subducted slab material that has penetrated into the lower mantle (from van der Hilst *et al.*, 1997).

Europe. Smaller-scale plume or slab features may also exist in the lower mantle, that are below the current resolution of seismic tomography. Innovative methods of scattering analysis or array imaging may prove to be the only means by which to constrain such structures (e.g., Ji and Nataf, 1998, Tilmann *et al.*, 1998; Tibuleac and Herrin, 1999).

While the lower mantle appears not to have internal layering, it has been proposed that the downward transition in heterogeneity pattern from a midmantle dominated by slab-like structures to a deep mantle dominated by large-scale high and low velocity features is caused by compositional stratification. In this model (see Kellogg *et al.*, 1999; van der Hilst and Kárason, 1999), the lowermost mantle is compositionally distinct, being composed of undifferentiated, “primordial” mantle material which is the source of isotopic anomalies sampled by major hotspot plumes. Downwelling slabs can depress the chemical boundary by hundreds of kilometers, deflecting it from a depth of around 2000 km. The postulated chemical boundary is not a strong reflector, and does not give rise to coherent features in the radially averaged mantle model. The density increase of the deep layer could be due to enrichment in iron or silica, which have competing effects on the velocity structure. This is a highly speculative model, but can at least reconcile the current observations of the deep mantle seismic structure with geochemical observations. Significant improvement of our understanding of the lower mantle will come with reliable determination of density heterogeneity directly from simultaneous inversion of normal modes and gravity observations. A first step in this direction has been presented by Ishii and Tromp (1999). Although also very preliminary, this study found that high-density material is piled up in regions of uplift beneath the Pacific and Africa, which would require a significant chemical heterogeneity contribution to offset the thermal anomaly of the upwellings. Until the models improve it may even be premature to associate low velocities with upwellings, for chemical heterogeneity may indeed be very important in the deep mantle.

6. Core

The core comprises about 31.5% of the Earth's mass, and the density is such that the only plausible composition is primarily iron. The contrasts in density and viscosity between the lower mantle and the outer core are comparable to those found at the surface of Earth between air and rock and between ocean water and rock, respectively. This is a staggering thought, to step across the core–mantle boundary from ultradense silicates and oxides to relatively superdense iron alloy that has viscosity close to that of water. This profound chemical change was seismically detected early in the 20th century, and many studies have sought to constrain the properties of the molten outer core and the solid inner core. Much of the effort has been motivated

by the recognition that a geodynamo resides within the core, producing and sustaining the Earth's magnetic field. The geodynamo involves turbulent flow of the outer core alloy, geometrically constrained by the planet's rotation and the presence of the inner core, with the heterogeneous structure of the base of the mantle producing a variable heat flow boundary condition on the system. A brief summary of principal findings is presented here, with many additional details provided elsewhere (Chapter 56 by Song; Jacobs, 1987; Song, 1997; Creager, 2000).

6.1 Radially Averaged Structure

Average velocity and density structures for the core are shown in Figure 19, with smoothly increasing velocities in the outer and inner cores and finite shear velocity only in the inner core. The mean velocities of the outer core are tightly constrained by the well-defined travel-time branches of *PKP* and *SKS* phases (Fig. 1), and once again, the classic models of Jeffreys and Gutenberg (Fig. 2) are very similar to contemporary models for the outer core. The outermost portion of the outer core is best constrained by *SKS* and *SKnS* phases, which have continuous turning points just below the CMB because the *P* velocity of the outer core is higher than the *S* velocity at the base of the mantle (e.g., Hales and

FIGURE 19 Seismologically measured density (bold solid curve), and compressional (V_p) and shear (V_s) elastic wave velocities in km sec^{-1} (thin lines) through the core and lowermost mantle shown as functions of depth and corresponding pressure. Extremal bounds on the V_p profile through the core are included for comparison. The difference between the polar (N-S) and equatorial (Eq.) compressional velocities through the inner core are indicated by dotted lines. Heterogeneity in the D' region is illustrated by variations in V_p and V_s profiles. (Reproduced with permission, from Jeanloz, 1990, © Annual Review Inc.)

Roberts, 1971). Studies of *SKS-S*, *SKKS-SKS* and *SKKKS-SKS* differential times have raised the possibility that a thin region with reduced velocity gradient exists in the outermost 50–100 km of the core (e.g., Hales and Roberts, 1971; Lay and Young, 1990; Souriau and Poupinet, 1991; Garnero *et al.*, 1993; Tanaka and Hamaguchi, 1993; Garnero and Lay, 1998). The issue is still open, but it is clear that if there is any core-side boundary layer it is very subtle and likely to involve only 0.5–1.0% anomalies in a thin layer.

Jeffreys and Bolt interpreted precursors to *PKP* phases in terms of complex inner core–outer core transition models, but these phases are now interpreted as the result of scattered phases from *D''*, and much simpler models of this transition near 5150 km depth are preferred. Generally, global average Earth models have smooth outer core velocity gradients right down to the inner core boundary, consistent with self-compression of the outer core alloy, however, several studies have suggested the presence of a transition zone with reduced gradients just above the boundary (e.g., Souriau and Poupinet, 1991; Song and Helmberger, 1992;). The contrasts at the boundary are best constrained using waveform modeling of reflections and diffractions, with recent studies preferring simple models (e.g., Cummins and Johnson, 1988; Shearer and Masters, 1990; Song and Helmberger, 1995). The *P* and *S* velocities are almost constant within the inner core on average. The *S* velocity, first constrained by normal mode modeling (e.g., Dziewonski and Gilbert, 1971) is around 3.6 km sec^{-1} . Direct observation of body waves that traverse the inner core as shear waves has been very difficult, but some candidates have been reported (e.g., Julian *et al.*, 1972; Okal and Cansi, 1998; Deuss *et al.*, 2000). The density of the inner core appears to be several percent lower than the density of pure iron, indicating the presence of some lighter elements (Jephcoat and Olson, 1987), whereas the outer core is about 10% less dense than pure iron (Masters and Shearer, 1990), with the light alloying component probably being H, C, S, O, Mg, and/or Si.

The outer core has a very high Q_α value, from 3000 to 10000+, and short-period seismic energy can travel great distances, including multiple underside reflections from the core–mantle boundary, with little anelastic attenuation (e.g., Engdahl, 1968; Adams, 1972; Cormier and Richards, 1973; Tanaka and Hamaguchi, 1996). However, the inner core has low Q_α , on the order of 200–360, which strongly attenuates short-period phases that penetrate into it (e.g., Doornbos, 1974, 1983; Cormier, 1981; Choy and Cormier, 1983; Bhattacharyya *et al.*, 1993; Song and Helmberger, 1995a). The attenuation of short-period signals may in part be caused by scattering rather than intrinsic attenuation (e.g., Cormier *et al.*, 1998; Vidale and Earle, 2000) because normal modes do not require very low *Q* values (e.g. Widmer *et al.*, 1991). The inner core indeed displays significant heterogeneity and seismic anisotropy, whereas there is no convincing evidence for either in the outer core.

6.2 Anisotropy and Heterogeneity of the Inner Core

Both body waves and normal modes indicate that the inner core is heterogeneous and anisotropic in its structure. Observations of anomalously split normal modes (e.g., Masters and Gilbert, 1981) and patterns in *PKIKP* arrival times (Poupinet *et al.*, 1983) laid the foundation for the first studies to propose the presence of anisotropy in the inner core (Woodhouse *et al.*, 1986; Morelli *et al.*, 1986). Although alternate models of aspherical structure in the outer core have been considered, there is now consensus that inner core structure can account for the normal mode (e.g., Tromp, 1993, 1995) and *PKIKP* data (e.g. Song, 1997; Creager, 1999). The latter phases travel 5–6 sec faster along the spin axis than across the equatorial plane (e.g., Creager, 1992; Song and Helmberger, 1993, 1995b, 1998; Vinnik *et al.*, 1994; Shearer, 1994; Su and Dziewonski, 1995; McSweeney *et al.*, 1997; Creager, 1999; see the reviews by Song, 1997 and Creager, 2000). The *PKIKP* data have established that there are large-scale lateral heterogeneities in the inner core associated with the anisotropy, with hemispherical patterns that extend all the way to the center of the Earth (e.g., Tanaka and Hamaguchi, 1997; Creager, 1999). The western hemisphere is 2–4% anisotropic on average. The anisotropy may be the result of crystal alignment induced by magnetic fields, convection, crystallization processes, or other effects not yet understood. Some of the structural complexity may also be associated with radial layering of the inner core (e.g., Song and Helmberger, 1998), but mapping out the surprising complexity of the inner core is still underway.

6.3 Rotation Rate of the Inner Core

The existence of heterogeneity and anisotropy within the inner core of the Earth allows a test of the stability of such patterns over time. This is of interest because it is uncertain whether the rotation of the inner core is locked to that of the mantle, and models for the geodynamo predict that there may be some differential rotation due to torques applied to the inner core. Song and Richards (1996) observed temporal variation in *PKIKP-PKP* differential times for observations on a path near the fast direction along the spin axis, with about 0.3 s change over 30 years. Assuming symmetry of the anisotropic fabric in the inner core, they inferred a 1.1° y^{-1} eastward (faster) relative rotation of the inner core. Su *et al.* (1996) used a lower quality data set with better spatial distribution, and inferred a 3° y^{-1} relative rotation rate. Subsequent work has extended the high quality data set, along with discarding the inadequate assumption of symmetry of the anisotropic pattern and allowing for small-scale structure in the inner core or near *D''* that may enhance or reduce the rate of change of differential time measurements (e.g., Creager, 1997; Souriau *et al.*, 1997; Laske and Masters, 1999; Souriau and

Poupinet, 2000; Poupinet *et al.*, 2000; Song and Li, 2000; Song, 2000; Vidale *et al.*, 2000). The more recent studies, reviewed by Creager (2000), suggest an inner core differential rotation rate of 0.2 to 0.6°y^{-1} , with some evidence favoring no relative rotation, but the evidence for relative rotation at a rate of about 0.2°y^{-1} is quite compelling. More discussion of this topic is found in Chapter 56 by Song.

7. Conclusions

This summary of basic attributes of the Earth's interior determined by seismology has only scratched the surface of the detailed knowledge acquired over the past century, and no overview of this length could begin to do full justice to the vast literature and many contributors who have played important roles in building this knowledge. However, this is a good starting point for delving into the topic, and the many references provide multiple pathways to the full body of seismological information. It should be clear that during the past century many first-order questions about the interior have been resolved, and there is good general consensus on basic issues of layering of the planet. However, there are many fundamental questions that remain open, and progress in the future will build upon the foundations described in this text. It is generally accepted that future advances will come from a combination of advances in wave propagation theory, development of new waveform inversion methods (and computing capabilities), increases in high quality seismic data acquired on multiple scales around the world, and by introduction of creative strategies for solving seismological problems. Equally well accepted is the notion that seismologists must increase their interactions and communications with mineral physicists and geodynamicists, building new interdisciplinary approaches to parameterizing and constraining structures and processes in the Earth's interior. The next century will see profound advances in our understanding, of that we can be assured, but all seismologists should study and contemplate the achievements of the many seismologists who contributed to the great first century of exploring the Earth's interior.

Probing the Earth's Interior with Seismic Tomography

Andrew Curtis

Roel Snieder

Colorado School of Mines, Golden, USA

1. Introduction

Seismological data recording the oscillations of seismic waves at distinct locations on the Earth's surface can be used to infer variations in elastic properties and density within the Earth. Creating images or models of these variations is called seismic tomography. Figure 1 shows examples of different seismic wave types that are used routinely to estimate Earth structure. Interface waves propagate along interfaces within the Earth. They oscillate with an amplitude that decays with distance from the interface and are effected by (and hence contain information about) structure around that interface. Surface

waves are a particular case that are generally classified as either Love waves which oscillate transversely (perpendicular to the path of propagation) or Rayleigh waves which oscillate elliptically in the vertical–longitudinal (parallel to the propagation path) plane. The longer the wavelength of surface waves, the deeper in the Earth they oscillate. The very long wavelength limit of surface waves are normal modes which vibrate the whole circumference of the Earth simultaneously, much like a ringing bell; the resonant frequencies with which they vibrate contain information about the structure of the whole Earth averaged in different ways. Many different body waves are distinguished (at the very least, *P*-compressional and *S*-shear waves), but all propagate through the Earth's interior and either refract, diffract or reflect energy due to elastic parameter or density variations. Hence body-wave data contain information about both interface and bulk properties of the Earth.

This chapter describes in detail the relationships between the character of body or surface wave propagation or of normal mode oscillations, and variations in subsurface Earth structure (the Earth model). It shows how, and under what conditions these relationships can be linearised; this allows linearised inverse theory to be used to estimate the structure from data recording the oscillations of such waves. However, an estimated model of Earth structure may be of little use unless we know the extent to which that estimate reflects the true Earth structure. We discuss how the inverse theory used and how the physics of seismic wave propagation limit the quality of the retrieved Earth model. We will see that constructing model estimates requires excellent data quality and stringent conditions to be fulfilled on the spatial distribution of the data. We show that these conditions can be used to *design* ideal seismological surveys. Finally, we show examples of surface-wave and body-wave tomography and illustrate that

FIGURE 1 Various wave types excited by an earthquake (star) in a subduction zone and recorded at a station (square) that are often used for seismic tomography. Lithospheric plates are shaded in grey. For Rayleigh and Love waves, the general particle oscillation direction beneath the surface is drawn, while the propagation direction is shown above the surface; for the body wave only the path of energy propagation from earthquake to station is shown. “+” denotes particle oscillation perpendicular to the page, “H” denotes high frequency and “L” low frequency components. Note that low frequency surface waves generally travel faster than high frequency surface waves.

only recently are similar Earth structures “visible” using these different data types.

2. A Brief History of Seismic Tomography

The development of seismic tomography began with attempts to estimate the radial structure of the Earth. The travel times of seismic waves for an Earth model that depends on depth only are related by an Abel transform to the seismic velocity. The inverse Abel transform was used early in this century as a tool to determine the depth-dependent velocity in the Earth from travel-time measurements (Herglotz, 1907; Wiechert, 1910; Schlichter, 1932). Using the WKB-approximation for the structure of surface wave modes, Takahashi (1955, 1957) developed an inversion method to determine the seismic velocity as a function of depth from the phase velocity of Love waves or Rayleigh waves. This method was also based on the inverse Abel transform.

Thus, the field of seismic tomography began with a method where an analytical technique, the inverse Abel transform, was used to infer the seismic velocity. In the Earth sciences, analytical techniques for creating tomographic images are not very useful. The reason for this is that in a realistic tomographic experiment, sources and receivers are distributed inhomogeneously and the reference model used in the tomography is often also inhomogeneous.

This situation is very different from examples in medical tomography where the source–receiver geometry has many degrees of symmetry and where the reference model is usually homogeneous. The resulting symmetry of the wave paths in medical tomography allows analytical methods, such as the Radon transform (Barrett, 1984), to be used to reconstruct the medium (Natterer, 1986). This high degree of symmetry also makes it possible for the medical equipment to carry out much of the data processing automatically. Because of the lack of symmetry in most seismic tomographic experiments, the reconstruction of the medium requires the solution of very large systems of equations (see Section 4). For this reason, computational challenges have been a central focus of early developments in seismic tomography.

The earliest applications of seismic tomography in its modern form employed array data (Aki and Lee, 1976; Aki *et al.*, 1977). In these studies the local lithospheric structure under the array was inferred from observed anomalies of seismic waves. In contrast to medical imaging, in seismic tomography one has no control over the source locations if earthquakes are used to generate the seismic waves. This has led, for example, Aki and Lee (1976) and Spencer and Gubbins (1980) to include the source location and origin time in the tomographic inversion. Up to the early 1980s, seismic tomography for the 3D Earth structure was based almost

exclusively on the arrival times or dispersion properties of seismic waves. The amplitude of seismic waves is influenced by the spatial derivatives of the seismic velocity since these derivatives determine the focusing of seismic waves. This effect was used by Thomson and Gubbins (1982) who developed a method of seismic tomography that treated the amplitude of seismic waves as extra relevant data.

It has been customary to solve the large systems of equations required for seismic tomography iteratively. Such methods are particularly attractive because the linear equations that must be solved are sparse when the seismic velocity is parameterized with a cell model (see Section 4). Initially, row-action methods were used where one row of the matrix at a time is used to update the model vector. Nolet (1985) introduced the more efficient conjugate gradient method to seismic tomography, where search directions in model space are updated in an efficient way. An overview of the numerical methods used to solve the linear equations of seismic tomography is given by van der Sluis and van der Vorst (1987).

With the growth in computing power and in the amount of seismological data available, it soon became possible to carry out seismic tomography on a global scale. Global images of the lower mantle were constructed by Dziewonski (1984) and by Comer and Clayton (1984). A global image for the upper mantle was presented in the same year by Woodhouse and Dziewonski (1984). These studies played an important role in the development of global tomography.

After 1984 the development of seismic tomography was extremely rapid. Refinements and improvements were made to tomographic inversion schemes. These developments include more detailed tomography on a global scale (Tanimoto and Anderson, 1985), the use of algorithms for waveform tomography (e.g., Nolet *et al.*, 1986; Tanimoto, 1987; Snieder, 1988a,b; Nolet, 1991) and the incorporation of ray-bending effects in seismic travel-time tomography (e.g., Bregman *et al.*, 1989; Sambridge, 1990). An essential element in the growth and use of seismic tomography has been the dramatic increase in the size of the tomographic problems that could be solved. Spakman *et al.* (1993) used more than half a million travel times to estimate the subsurface structure under Europe and the Mediterranean with an unprecedented resolution.

This brief overview of the history of seismic tomography cannot do justice to the numerous contributions to this field that have been made by a large number of researchers. Review articles have appeared that focus on global tomography (Dziewonski and Woodhouse, 1987) as well as regional tomography (Romanowicz, 1991) and on the implications of seismic tomography on the dynamics of the Earth’s mantle (Montagner, 1994). In addition, a number of textbooks give a comprehensive overview of the different aspects of seismic tomography (Nolet, 1987; Iyer and Hirahara, 1993; Morelli *et al.*, 1996; Dahlen and Tromp, 1998). The interested reader is encouraged to consult these texts for further information.

3. Linearising the Model–Data Relationships

In general, seismological data depend in a complicated, nonlinear way on the Earth model about which we seek information. The associated nonlinear inverse problem (see Section 4) of constraining the model by the data is usually difficult to solve, and there are no foolproof systematic algorithms that find correct solutions. It is for this reason that linear approximations play a central role in seismic tomography: after linearising the model–data relationship, one can draw on results from linear algebra to constrain the model (Section 4).

In this section three important linearisations are described. In Section 3.1 the Born approximation is introduced; this gives the first-order distortion of the entire wave-field due to model perturbations. The first-order effect of slowness perturbations on the arrival time of waves has its root in Fermat's principle as described in Section 3.2. The linearised imprint of Earth structure perturbations on its normal mode eigenfrequencies is introduced in Section 3.3.

In all cases, linearisations are approximations to the true nonlinear model–data relationships; these approximations are valid when the difference between the true Earth structure and our best initial guess at the structure (our reference model) are relatively small. Whether the true Earth structure is sufficiently close to our current best estimates that correct solutions can be found using linearised methods is still an open question.

3.1 The Born Approximation

The Born approximation is introduced here using the example of the Helmholtz equation that describes acoustic wave propagation:

$$\left(\nabla^2 + \frac{\omega^2}{c^2(\mathbf{r})}\right)p(\mathbf{r}) = F(\mathbf{r}) \quad (1)$$

In this expression $F(\mathbf{r})$ describes the source signal at angular frequency ω that excites the wave-field $p(\mathbf{r})$ which then propagates through a medium with velocity $c(\mathbf{r})$. This equation is not appropriate to describe the propagation of elastic waves in the Earth, but it contains the essential elements to convey the principle of the Born approximation with fewer complications.

Central to the Born approximation is the separation of the model into a reference model and a perturbation. In this example, $1/c^2(\mathbf{r})$ is decomposed into a constant reference velocity c_0 and a perturbation:

$$\frac{1}{c^2(\mathbf{r})} = \frac{1}{c_0^2} [1 + n(\mathbf{r})] \quad (2)$$

Heterogeneity in the model is therefore described by the perturbation $n(\mathbf{r})/c_0^2$. The second ingredient needed for the Born approximation is the response of the unperturbed medium to a point force excitation at any arbitrary location $\mathbf{r}'$. This particular response is called the Green's function; by definition it satisfies the wave Eq. (1) for the reference medium and a point force excitation at $\mathbf{r}'$:

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)G_0(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}') \quad (3)$$

This Green's function can be used to find the unperturbed wave $p_0(\mathbf{r})$ that propagates through the reference medium c_0 . The unperturbed wave satisfies Eq. (1) with the velocity $c(\mathbf{r})$ replaced by the unperturbed velocity:

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)p_0(\mathbf{r}) = F(\mathbf{r}) \quad (4)$$

The wave-field $p_0(\mathbf{r})$ at point $\mathbf{r}$ which is excited by the excitation F and which propagates through the reference medium c_0 can then be expressed in terms of this Green's function

$$p_0(\mathbf{r}) = \int G_0(\mathbf{r}, \mathbf{r}') F(\mathbf{r}') dV' \quad (5)$$

where the integral is over the volume containing all sources of excitation. The life-history of the unperturbed wave can be followed by reading this expression from right to left. At the source location $\mathbf{r}'$ the wave is excited by the excitation $F(\mathbf{r}')$. The unperturbed Green's function $G_0(\mathbf{r}, \mathbf{r}')$ describes how this wave propagates from the point of excitation $\mathbf{r}'$ to the point $\mathbf{r}$.

In order to find the waves scattered by perturbations to the reference model we write the total wave field as the sum of the unperturbed wave p_0 and the scattered waves p_S :

$$p(\mathbf{r}) = p_0(\mathbf{r}) + p_S(\mathbf{r}) \quad (6)$$

Inserting this expression and the decomposition (2) in Eq. (1) gives

$$\begin{aligned} \left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)p_0(\mathbf{r}) + \left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)p_S(\mathbf{r}) + \frac{\omega^2}{c_0^2}n(\mathbf{r})p_0(\mathbf{r}) \\ + \frac{\omega^2}{c_0^2}n(\mathbf{r})p_S(\mathbf{r}) = F(\mathbf{r}) \end{aligned} \quad (7)$$

Using Eq. (4) for the unperturbed wave this result can be written as

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)p_S(\mathbf{r}) = -\frac{\omega^2}{c_0^2}n(\mathbf{r})p_0(\mathbf{r}) - \frac{\omega^2}{c_0^2}n(\mathbf{r})p_S(\mathbf{r}) \quad (8)$$

The last term in the right hand side contains the cross-product of the scattered wave $p_S(\mathbf{r})$ and the perturbation $n(\mathbf{r})$, hence this term is nonlinear in the perturbation of the medium. In the

Born approximation one linearises the relation between the scattered waves and the perturbation of the medium, which means that the last term in Eq. (8) is ignored. Physically this corresponds to ignoring the multiple scattering effects. The resulting expression for the scattered waves is denoted with $p_B(\mathbf{r})$, where B stands for *Born*. In the Born approximation the scattered waves thus satisfy

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2}\right)p_B(\mathbf{r}) = -\frac{\omega^2}{c_0^2}n(\mathbf{r})p_0(\mathbf{r}) \quad (9)$$

This expression is of the same form as Eq. (4), the only difference is that the right hand side is not given by the excitation $F(\mathbf{r})$ but by a term proportional to $n(\mathbf{r})p_0(\mathbf{r})$. Physically this corresponds to the fact that the perturbation of the medium can be seen as the source of the scattered waves and that this excitation is proportional to the wave field at the location of the scatterers. Equation (9) can also be solved using the unperturbed Green's function to give:

$$p_B(\mathbf{r}) = -\int G_0(\mathbf{r}, \mathbf{r}') \frac{\omega^2 n(\mathbf{r}')}{c_0^2} p_0(\mathbf{r}') dV' \quad (10)$$

Just as for Eq. (5), this expression can be interpreted by reading it from right to left. The wave field $p_0(\mathbf{r}')$ is excited and propagates through the unperturbed medium to the perturbation of the medium at location $\mathbf{r}'$. At this point the wave is scattered with a scattering coefficient $-\omega^2 n(\mathbf{r}')/c_0^2$ that depends linearly on the perturbation. The Green's function then describes how the scattered wave propagates to location $\mathbf{r}$.

It should be emphasised that Eq. (10) is an approximation. In reality the wave field interacts repeatedly with the perturbations of the medium. Physically this corresponds to the double scattered waves, triple scattered waves, etc. The Born approximation retains only the single scattered waves. This is both its strength and its weakness; it leads to a linear relation for the effect of a model perturbation on the recorded data but the approximation has a limited range of validity. A full derivation of the multiple scattering series including the Born approximation is given by Snieder (2001).

The reasoning of this section is not specific to the Helmholtz equation. The only essential elements that are needed are: (1) the wave equation is linear, (2) the model can be divided in a natural way into a reference model and a perturbation and (3) the Green's function of the unperturbed problem can be computed. Exactly the same arguments can be applied to acoustic waves and electromagnetic waves (de Hoop, 1995), quantum mechanics (Mertzbacher, 1970), elastic body waves (Hudson, 1977), elastic surface waves (Snieder, 1986a,b) and the Earth's normal modes (Dahlen and Tromp, 1998). The latter applications are of great importance to seismology.

3.2 Fermat's Theorem

Travel-time tomography uses the arrival times of elastic waves to infer the velocity in the Earth. The basic principle is very

simple; the travel time is the integral of the slowness along the ray-path:

$$T = \int_{\mathbf{r}[u]} u(\mathbf{r}) ds \quad (11)$$

In this expression u is the slowness which is defined as the inverse of the velocity: $u = 1/c$. The travel time T can be measured from recorded data and the aim of travel-time tomography is to infer the slowness u from these data. Equation (11) suggests that this is a simple problem because the travel time and the data are related linearly. There is, however, a catch. Rays are curves that render the travel time measured along the curve stationary with respect to the curve position. This means that the ray along which the slowness in Eq. (11) is integrated also depends on the (unknown) slowness. This makes the relation between the travel time and the slowness in Eq. (11) nonlinear.

Fortunately, the relation between the travel-time perturbation and the slowness perturbation can be linearised in a simple way. Just as in Section 3.1 the model is divided into a reference model and a perturbation

$$u(\mathbf{r}) = u_0(\mathbf{r}) + u_1(\mathbf{r}) \quad (12)$$

and the travel time is decomposed into the travel time T_0 through the reference medium u_0 and a travel-time perturbation δT :

$$T = T_0 + \delta T \quad (13)$$

The traditional way to derive the linearised relation between the travel-time perturbation and the slowness perturbation given in Eq. (14) is to invoke Fermat's theorem. This theorem states that the travel time to first order does not depend on changes in the ray position (e.g., Ben-Menahem and Singh, 1981; Nolet, 1987). The proof of this theorem relies on variational calculus and is unnecessarily complex. An alternative derivation of the linearised relation between δT and u_1 is given in a very short and elegant derivation by Aldridge (1994) who shows that to first order

$$\delta T = \int_{\mathbf{r}_0[u_0]} u_1(\mathbf{r}_0) ds_0 \quad (14)$$

The derivation does not use Fermat's theorem explicitly, but does use the fact that the travel time is stationary under ray perturbations. This derivation can also be extended to include higher-order travel-time perturbations (Snieder and Sambridge, 1992; Snieder and Aldridge, 1995). The crux of Eq. (14) is that the integration of the slowness perturbation is now taken over the reference ray $\mathbf{r}_0$ in the reference medium. Since the rays in the reference medium are known (because the reference medium is known), Eq. (14) constitutes a linear relation between the travel-time perturbation and the slowness perturbation.

FIGURE 2 Diagram of a tomographic experiment.

The simplest way to implement Eq. (14) in tomographic inversions is to divide the models into cells and to assume that the slowness perturbation is constant in every cell. When the travel-time data are denoted with the subscript i and the cells with the subscript j the discretized form of the integral (14) is given by:

$$\delta T_i = \sum_j L_{ij} u_j \quad (15)$$

where u_j now denotes the slowness perturbation in cell j , and L_{ij} denotes the length of ray number i through cell number j as defined in Figure 2. This means that the inverse problem reduces to the problem of solving a system of linear equations.

By solving Eq. (15) we perform a single linear inversion. The solution comprises a set of slowness perturbations u_j , one in each cell, which can then be added to the slownesses of the reference model. Thus we obtain an updated reference model. Ray paths can be recalculated in the updated medium leading to a new set of linear equations of the form in Eq. (15). Solving these provides a second set of slowness perturbations to be added to the updated reference model, and so on. This iterated, linearized inversion process is often used in ray-path tomography in the hope that the solution accuracy increases with each iteration (e.g., Bijwaard and Spakman, 2000). Note, however, that there is no guarantee that this will be true.

3.3 Rayleigh's Principle

Other data that constrain the internal structure of the Earth are the normal-mode eigenfrequencies of the Earth and the phase or group velocity measurements of surface waves. These data can all be seen as the eigenvalues of a system of differential equations for the motion in the Earth with appropriate boundary conditions. In this section we refer to the normal-mode frequencies or the surface-wave dispersion measurements as λ_i .

In general, the relation between these eigenvalues and the associated velocity model is nonlinear, which complicates

the inverse problem. As in Sections 3.1 and 3.2 the Earth model can be decomposed into a reference model m_0 and a perturbation m_1 . The reference model has eigenvalues $\lambda_i^{(0)}$ that are perturbed with a perturbation $\delta\lambda_i$. The relation between the perturbations of the eigenvalues and the perturbations of the Earth model can be linearised using Rayleigh's principle (Woodhouse, 1976). This states that, to first order the perturbation of the eigenvalues depends linearly on the perturbation of the Earth model and on the modes in the reference Earth model. Since the modes in the reference Earth model are assumed to be known, the inverse problem can be seen as the solution of a linear system of equations.

For example, for surface waves it can be shown (e.g., Takeuchi and Saito, 1972; Aki and Richards, 1980) that the phase velocity perturbation of surface waves is related to the perturbations in shear velocity $\delta\beta$, compressional velocity $\delta\alpha$ and density $\delta\rho$ by the relation

$$\frac{\delta c}{c} = \int K_\beta(z) \frac{\delta\beta(z)}{\beta(z)} dz + \int K_\alpha(z) \frac{\delta\alpha(z)}{\alpha(z)} dz + \int K_\rho(z) \frac{\delta\rho(z)}{\rho(z)} dz \quad (16)$$

which holds at each location on the Earth's surface. In this expression the kernels $K(z)$ depend only of the reference model and can be assumed to be known (e.g., see Fig. 5). Again, the relation between the data δc and the model perturbations $\delta\beta$, $\delta\alpha$ and $\delta\rho$ is linear. After discretisation this leads to a linear system of equations of the form of Eq. (15) that is relatively easy to solve. Expressions similar to Eq. (16) hold for the Earth's normal modes leading to an equally simple system of equations to solve (Woodhouse, 1980; Woodhouse and Dahlen, 1978).

4. Tomographic Inversion

Performing tomography inevitably involves the use of inverse theory. Since the number of data and model parameters is often very large, linearised physics and the relatively efficient linearised form of inverse theory from the field of linear algebra are usually used. However, to evaluate the quality of any tomographic solution found, it is important that we understand the strengths and limitations of this theory which we illustrate below. Further details can be found in Matsu'ura and Hirata (1982), Tarantola and Valette (1982a,b), Tarantola (1987) or Parker (1994).

4.1 Linearised Inverse Theory

The true Earth structure has more detail than any finite set of observations can resolve. Say we construct an infinite and complete set of basis functions $\{\mathbf{B}_j(\mathbf{x}); j = 1, \dots, \infty\}$ such that

any possible model $\mathcal{M}$ of Earth structure at location $\mathbf{x}$ could be expressed as:

$$\mathcal{M}(\mathbf{x}) = \sum_{j=1}^P m_j \mathbf{B}_j(\mathbf{x}) \quad (17)$$

where $P = \infty$. The tomographic problem then consists of estimating coefficients $\mathbf{m}' = [m_1, \dots, m_P]$. Unfortunately only a finite amount of data is ever measured, so usually we restrict the model to a finite subset of the basis functions (i.e., P finite); these functions span only those features of Earth structure that are important to us and which might be resolvable by the available data. For this purpose, basis functions commonly employed in seismology are mutually exclusive polygonal cells ($B_j(\mathbf{x}) = 1$ if $\mathbf{x} \in \text{cell } j$, 0 otherwise), orthogonal splines, or spherical harmonics for global models.

Suppose seismological data are recorded at a set of seismic receivers, possibly using artificial seismic sources. In the previous section we showed that in some situations such data can be related approximately to an appropriately parameterised Earth model using linearised physical relationships for models close to an initial model estimate $\mathbf{m}_0$. Let the recorded data be denoted by $\mathbf{d}_{\text{rec}}$, and let $\mathbf{F}(\mathbf{m}')$ represent the forward function that predicts the recorded data for a given model $\mathbf{m}'$. The recorded data differ from the data $\mathbf{d}_0 = \mathbf{F}(\mathbf{m}_0)$ calculated for the initial model estimate $\mathbf{m}_0$ because the true Earth structure differs from the initial model, and because the recorded data are contaminated with errors $\mathbf{e}$. In the remainder we refer to the difference between the recorded data and the reference data $\mathbf{d}_0$ for the initial model as “the data” $\mathbf{d}$:

$$\mathbf{d} \equiv \mathbf{d}_{\text{rec}} - \mathbf{d}_0 \quad (18)$$

Let the true Earth model be denoted $\mathbf{m}_{\oplus}$ [using the infinite-dimensional basis in Eq. (17) with $P = \infty$] and let its projection onto the (usually finite-dimensional) space of basis functions used for $\mathbf{m}_0$ be denoted $\mathbf{m}_r$. The difference between $\mathbf{m}_r$ and the reference model $\mathbf{m}_0$ is referred to as “the model” $\mathbf{m}$:

$$\mathbf{m} \equiv \mathbf{m}_r - \mathbf{m}_0 \quad (19)$$

Using the relation $\mathbf{d}_{\text{rec}} = \mathbf{F}(\mathbf{m}_{\oplus}) + \mathbf{e}$ the relation between the data and model as defined in Eqs. (18) and (19) can be linearised:

$$\begin{aligned} \mathbf{d} &= \mathbf{d}_{\text{rec}} - \mathbf{d}_0 = \mathbf{F}(\mathbf{m}_{\oplus}) - \mathbf{F}(\mathbf{m}_0) + \mathbf{e} \\ &\approx \mathbf{A}(\mathbf{m}_r - \mathbf{m}_0) + \mathbf{e} \\ &= \mathbf{A}\mathbf{m} + \mathbf{e} \end{aligned} \quad (20)$$

The matrix $\mathbf{A}$ describes the linearisation of the full physical model–data relationship $\mathbf{F}$ (elements are $A_{ij} = \partial F_i / \partial m_j$) and depends on the data types used, the basis functions and the seismic source and receiver locations (the survey design).

The generalised least-squares solution of Eq. (20) is defined to be the one that minimises the squared misfit function E :

$$E = (\mathbf{d}_{\text{rec}} - \mathbf{F}(\mathbf{m}))^T \mathbf{W}_d (\mathbf{d}_{\text{rec}} - \mathbf{F}(\mathbf{m})) + \lambda \mathbf{m}^T \mathbf{W}_m \mathbf{m} \quad (21)$$

$$\simeq (\mathbf{d} - \mathbf{A}\mathbf{m})^T \mathbf{W}_d (\mathbf{d} - \mathbf{A}\mathbf{m}) + \lambda \mathbf{m}^T \mathbf{W}_m \mathbf{m} \quad (22)$$

E has two components: the first term measures the squared misfit between the observed data (perturbation) $\mathbf{d}$ and the predicted perturbations $\mathbf{A}\mathbf{m}$ that are consistent with model $\mathbf{m}$, where different datum misfits can be weighted with a matrix $\mathbf{W}_d$ to reflect data uncertainty. This is added to λ times the norm of a quadratic combination of model $\mathbf{m}$ weighted by the matrix $\mathbf{W}_m$ (second term). Here $\mathbf{W}_d$ and $\mathbf{W}_m$ are positive definite, and λ is a trade-off parameter: minimising E with λ small gives a solution that preferentially fits the weighted measured data; with λ large the solution preferentially minimises the weighted model norm. The matrix $\mathbf{W}_m$ can be defined such that it causes the model to be either as smooth or as small (damped) as possible for instance. Adding this term is known as regularising the solution (Tikhonov, 1963). A simple piece of algebra (see Snieder and Trampert, 2000) shows that the minimum E occurs at

$$\mathbf{m}_{\text{est}} = (\mathbf{A}^T \mathbf{W}_d \mathbf{A} + \lambda \mathbf{W}_m)^{-1} \mathbf{A}^T \mathbf{W}_d \mathbf{d} \quad (23)$$

When no regularisation is applied ($\lambda = 0$) the matrix inverse taken in Eq. (23) usually does not exist. This reflects the fact that the inverse problem is ill-posed (there are insufficient data to constrain the model). The amount of regularisation that one applies should ensure that the inverse matrix in Eq. (23) is well behaved. As an alternative one can replace the matrix inverse in Eq. (23) by an approximation of the matrix inverse that is devoid of small eigenvalues (see Matsu'ura and Hirata, 1982; Menke, 1989; Parker, 1994). However, stabilising the inverse problem by an explicit regularisation has the advantage that one controls and understands better the effects of regularisation.

4.2 Assessing Quality of the Linearised Solution

The inverse problem is usually treated first as a model estimation problem followed by an assessment of how the estimated model is related to the true Earth model (the appraisal problem, Snieder, 1998). Although the solution [Eq. (23)] solves the problem of estimating Earth structure $\mathbf{m}_{\text{est}}$ from data $\mathbf{d}$, it is necessary to assess how good an approximation to the true Earth structure $\mathbf{m}_{\oplus}$ that this provides. We now explore the factors that cause the accuracy of $\mathbf{m}_{\text{est}}$ to deteriorate.

First, the data in Eq. (23) are usually contaminated with errors about which our only information is statistical [Eq. (20)]. These errors are mapped onto the estimated model, so model statistics are needed to indicate features in the estimated model that may be caused by errors in the data. The way in which

errors in the data propagate into the model depends on the regularization. This follows from Eq. (23): the solution $\mathbf{m}_{\text{est}}$ depends on the type and strength of regularisation applied. The form of matrix $\mathbf{W}_m$ defines the type of regularisation and often there is no objective reason to prefer any particular form. Even once a form for $\mathbf{W}_m$ has been chosen, there is generally no objective way to choose λ unless a physical meaning is attributed to the weight matrices in terms of the probability distributions of noise $\mathbf{e}$ and models $\mathbf{m}$ (Tarantola and Valette, 1982a; Matsu'ura and Hirata, 1982; Tarantola, 1987). However, often even this strategy is impossible to apply objectively (Scales and Snieder, 1997), so in practice a degree of subjectivity is inevitable in all tomographic Earth models.

The second source of error comes from the linearised inverse theory itself. Figure 3(a) illustrates the process of finding a solution to a linearised system for one model parameter for $\lambda=0$. Beginning at the reference model $\mathbf{m}_0$ we calculate $\mathbf{d}_0 = \mathbf{F}(\mathbf{m}_0)$ and hence the required data perturbation $\mathbf{d}$, and the linear operator $\mathbf{A}$ (the gradient) as illustrated previously. Assuming the physical relationship $\mathbf{F}$ is approximately linear, the gradient is used to extrapolate away from $\mathbf{m}_0$ to estimate the true model $\mathbf{m}_0 + \mathbf{m}$ that minimises the quadratic data misfit E given by Eq. (22). The data uncertainty (here represented by $\pm$ bounds, but more generally a data probability distribution) is mapped into a linearised model uncertainty by projecting it through the (linearised) physics.

Notice, for later on, that for the same data uncertainty, the projected model uncertainty would diminish if $\mathbf{F}(\mathbf{m})$ was steeper (roughly speaking, if $\mathbf{A}$ was larger in some sense to be defined later). This can be shown explicitly when the data uncertainties and prior model distributions are Gaussian ($\mathbf{C}_m = \mathbf{W}_m^{-1}$ and $\mathbf{C}_d = \mathbf{W}_d^{-1}$ are covariance matrices). Then

the model uncertainty after a truly linear Bayesian inversion is Gaussian with covariance

$$\mathbf{C} = (\mathbf{A}^T \mathbf{C}_d^{-1} \mathbf{A} + \mathbf{C}_m^{-1})^{-1} \quad (24)$$

(Tarantola and Valette, 1982a). In the case of one model parameter, $\mathbf{C}$ is reduced if the (single) gradient in $\mathbf{A}$ increases.

Figure 3(b) illustrates what can happen when $\mathbf{F}$ is not truly linear: if the reference model $\mathbf{m}_0$ is “close” to the unknown true solution $\mathbf{m}_t$ then generally the linearised step produces a model $\mathbf{m}_1$ that is closer to $\mathbf{m}_t$. Repeated linearised steps usually converge toward the solution. If the reference model is too far from the true solution (e.g., $\mathbf{m}_{0'}$) or if the problem is far from linear, this procedure may converge to a secondary solution (at a different misfit minimum). The linearised uncertainty estimates in each case give only the projected uncertainties around each solution found (one or other of the shaded areas in Fig. 3). The true uncertainty in both cases is more accurately described by the union of the three shaded projections: this union reflects our true state of uncertainty about the model, representing the complete subset of model space within which the data cannot discriminate. If the misfit E has n distinct minima, then the true uncertainty may comprise the union of n distinct regions of model space. Unfortunately n is seldom known or sought due to the comparatively large computational effort required for such a search. Hence, this source of error may cause not only erroneous model estimates, but invalid model uncertainty estimates.

A third source of error is caused by inherent non-uniqueness in the data recorded. Even if the inverse problem is truly linear and there are no errors in recorded data, there are usually features of the model that cannot be resolved. For example,

FIGURE 3 One-dimensional example of (a) linear and (b) linearised inversion. In each case, $\mathbf{m}_0$ represents the initial model chosen, and successive models found in the inversion process are shown as $\mathbf{m}_1$ and $\mathbf{m}_2$. $\mathbf{m}_t$ is the true model and the measured datum is $\mathbf{d}_t$ (with no errors in this case). The forward relationship $\mathbf{F}$ is shown in light grey and its gradient at specific points are represented by bold tangents with dashed linearised projections. The corresponding misfit function E [Eq. (21)] is shown in the lower plot of each pair. Horizontal axes always represent the model space (some labels omitted for clarity). Data uncertainties and their projections into the model space are represented by dark grey shading.

consider trying to constrain the seismic slowness of each cell in Figure 2 from a data set consisting of (noiseless) travel times along only the four ray paths shown; the data set is clearly insufficient to constrain the complete model.

In such cases, regularisation controls the otherwise unconstrained model features in our model estimate. Since the regularisation applied is usually chosen subjectively, these effects must be assessed. This is achieved by calculating the resolution matrix $\mathbf{R}$. This indicates how much information about the true Earth would be contained in estimate $\mathbf{m}_{\text{est}}$ for a given choice of $\mathbf{W}_m$, *if we had perfect data measurements and if the inversion was truly linear*. Hence, it represents a truly optimistic scenario! Its value lies in the fact that it describes the upper limit on our ability to estimate the true model due to the inherent deficiencies in the particular data set used. Substituting Eq. (20) into Eq. (23) one obtains the following relation between the estimated model and the true model:

$$\mathbf{m}_{\text{est}} = \mathbf{R} \mathbf{m}_t \quad (25)$$

where

$$\mathbf{R} = (\mathbf{A}^T \mathbf{W}_d \mathbf{A} + \lambda \mathbf{W}_m)^{-1} \mathbf{A}^T \mathbf{W}_d \mathbf{A} \quad (26)$$

If $\mathbf{R} = \mathbf{I}$ the estimated model is equal to the true model; as $\mathbf{R}$ deviates from $\mathbf{I}$ the estimate becomes an average of the true model weighted by resolution matrix $\mathbf{R}$. In nonlinear systems $\mathbf{R}$ is only valid locally around $\mathbf{m}_{\text{est}}$. Equation (26) seems to suggest that regularisation degrades the resolution; in the absence of regularisation ($\lambda = 0$) the resolution operator is given by $\mathbf{R} = (\mathbf{A}^T \mathbf{W}_d \mathbf{A})^{-1} \mathbf{A}^T \mathbf{W}_d \mathbf{A} = \mathbf{I}$. However, in practical problems in the absence of regularisation the inverse $(\mathbf{A}^T \mathbf{W}_d \mathbf{A})^{-1}$ does not exist, so one must use an approximate generalised inverse $(\mathbf{A}^T \mathbf{W}_d \mathbf{A})^{-g}$ instead. Since $(\mathbf{A}^T \mathbf{W}_d \mathbf{A})^{-g} (\mathbf{A}^T \mathbf{W}_d \mathbf{A})$ then differs from the identity matrix the resolution operator in that case also differs from the identity matrix. Usually a range of $\mathbf{W}_m$ is reasonable for any particular inversion so the resolution should be assessed for samples of $\mathbf{W}_m$ within this range (Rezovsky and Ritzwoller, 1999).

One final source of error must be considered, and this is derived from truncating expansion Eq. (17) to a finite set of P basis functions. If the true Earth structure $\mathcal{M}_t(\mathbf{x})$ contains some features that affect the recorded data but that cannot be represented within the truncated basis, these features will cause spurious errors in the finite-dimensional model solution $\mathbf{m}_{\text{est}}$ (an example is given later, see Color Plate 22). This process is called spectral leakage, and is caused by an inappropriate choice of the set of basis functions (Snieder *et al.*, 1991). Trampert and Snieder (1996) presented a solution to this problem under certain conditions, but the best way to solve it approximately is to ensure that the P chosen basis functions allow sufficient detail to model those features of $\mathcal{M}$ that have any significant influence on the data (if this is possible).

4.3 Computational Issues

Notice that each linearised iteration i in Figure 3(b) requires the calculation of the synthetic data and its gradient at model $\mathbf{m}_i$, plus a matrix inversion [Eq. (23)] or an approximation to solution (23) if this matrix is too large to be inverted (e.g., Paige and Saunders, 1982; Nolet, 1985; van der Sluis and van der Vorst, 1987). Assessing the true uncertainty in nonlinear problems (e.g., the union of the shaded regions in Fig. 3) requires computationally intensive nonlinear inversion methods such as repeated linearised inversion from many different starting models (Deng, 1997), Monte Carlo (e.g., Hammersley and Handscomb, 1964), or other types of stochastic nonlinear inversion methods (Sen and Stoffa, 1991, 1992; Vinther and Mosegaard, 1996; Douma *et al.*, 1996; Sambridge, 1998; Devilee *et al.*, 1999). All of these typically require the function $\mathbf{F}$ to be evaluated many thousands of times. This is currently impossible for common large inverse systems with complex physics which is the main reason why linearised physics, inversion, and uncertainty estimates are so widely used, despite their shortcomings described above.

5. Optimal Survey Design

We now show how seismic surveys can be designed such that the data collected allow the model to be constrained with minimum uncertainty using linearised inverse methods. We showed above how the effectiveness (quality) of tomography is usually estimated using the model resolution $\mathbf{R}$ and uncertainty $\mathbf{C}$, both of which depend on $\mathbf{W}_m$, $\mathbf{W}_d$, and $\mathbf{A}$ and both of which are valid only locally around any misfit minimum. Once the regularisation $\mathbf{W}_m$ and a value of λ has been fixed, and assuming that the model basis functions have been chosen carefully, the tomographic quality approximately depends only on the number of misfit minima n , on matrices $\mathbf{A}(\mathbf{m}_i)$ (the gradient of $\mathbf{F}(\mathbf{m}_i)$) at each misfit minimum $\mathbf{m}_i$; $i = 1, \dots, n$, and on data weights $\mathbf{W}_d$. In turn, all of these can only be influenced by varying the survey design.

Let $\mathbf{S} = [\mathbf{r}_1, \dots, \mathbf{r}_s]$ represent the survey design where the variables $\mathbf{r}_i$ might describe the source or receiver locations, the data bandwidth, data types recorded, the make of equipment used, the number of repeated measurements, etc., all of which might affect n , $\mathbf{A}(\mathbf{m}_i)$ or $\mathbf{W}_d$. To design surveys optimally requires that we have some measure Φ of survey quality. The design $\mathbf{S}$ can then be varied such that Φ is maximised.

Let us begin by assuming that the number of minima $n = 1$. Therefore, iterated linearised tomographic inversion should be robust (Fig. 3). The easiest way to measure survey quality for linearised inversion would be to define $\Phi[\mathbf{C}, \mathbf{R} - \mathbf{I}]$ to measure some balance between the linearised uncertainty estimate $\mathbf{C}$ and how closely the resolution matrix $\mathbf{R}$ resembles the identity $\mathbf{I}$. These, and related measures are discussed by, for example, Barth and Wunsch (1990), Atkinson and Donev

(1992), Maurer and Boerner (1998), and Curtis (1999a). Increasing the complexity slightly, these linearised techniques can be adapted to measure how information is distributed between particular targets of interest within the model space; by varying the design to alter this distribution, focused surveys can be designed (Curtis, 1999b).

Examples of unfocused and focused crosswell tomographic surveys are shown in Figure 4 and Color Plate 21(a) respectively. Figure 4 shows a tomographic survey and corresponding ray paths through a homogeneous reference model that give a high degree of information about the slowness structure across the whole interwell model space (Curtis, 1999a). Notice that the average density of sources and receivers generally increases down the length of each well, and across the surface the average density is half that within the wells. The survey shown in Color Plate 21(a) uses fewer sources and receivers and hence cannot resolve velocities in all of the model cells. Instead, this plot shows a survey that provides most information about (is focused on) the region of interwell space marked by the crosses (Curtis, 1999b). Notice that the ray paths are mainly focused within the relevant region (but also note that the focusing of ray paths alone is a poor criterion on which to design surveys, see Curtis and Snieder, 1997).

A crucial subtlety exists here: survey design, by definition, is carried out before data have been collected and hence before either a misfit function E or any inversion solution $\mathbf{m}_e$ exist. Hence, instead of evaluating $\mathbf{C}$ and $\mathbf{R}$ at misfit minima, they must be evaluated at our best prior estimate $\mathbf{m}_p$ of the solution. Clearly if the gradients $\mathbf{A}(\mathbf{m}_p)$ and $\mathbf{A}(\mathbf{m}_i)$ differ, the quality estimate will be in error; this is why such methods rely intrinsically on pseudo-linearity of the forward function $\mathbf{F}$.

One method to compensate partially for this problem is offered in the field of Bayesian statistical experimental design (e.g., Atkinson and Donev, 1992; Maurer and Boerner, 1998). Say all of our knowledge about the Earth model prior to inversion can be summarised by a prior probability distribution $\rho(\mathbf{m})$, then our best estimate of survey design quality is given by:

$$\bar{\Phi} = \int_{\mathcal{M}} \Phi(\mathbf{m}) \rho(\mathbf{m}) d\mathbf{m} \quad (27)$$

where $\Phi(\mathbf{m})$ is any measure of survey design quality evaluated at a specific model $\mathbf{m}$, similar to those measures discussed above for example. $\bar{\Phi}$ is called the Bayesian estimator of survey design quality. Designing experiments to maximise $\bar{\Phi}$ is the best we can do, given our (lack of)

FIGURE 4 Best unfocused crosswell survey geometry found. The left and right sides of the diagram represent vertical boreholes, the top represents the ground surface. Squares represent model cells, ray paths between sources and receivers are shown by straight lines. Twenty sources and twenty receivers were used in this example.

knowledge about the Earth model before we conduct the survey.

The measure in Eq. (27) averages over the different values of Φ which arise due to nonlinearity of $\mathbf{F}$. However, Curtis and Spencer (1999) illustrate that using a standard linearised quality measure for Φ similar to those described above does not circumvent the requirement that there is only a single misfit minimum – this is assumed in Eq. (27) since it is assumed for measure $\Phi(\mathbf{m})$. Hence, this expression only compensates for weak nonlinearity.

As explained earlier, in nonlinear inverse problems with multiple minima ($n > 1$), iterated linearised inversion converges to a single minimum and allows local uncertainty estimation, providing no indication of whether other possible solutions (other minima) exist. The only way to ensure the robustness of such inversions is therefore to change the misfit function such that it has a single minimum, and again this might be achieved by varying the survey design. This approach was demonstrated by Curtis and Spencer (1999) who varied the survey design such that the number of minima n was minimised. However, these methods are computationally very expensive and so far they have only been applied to problems with few model parameters.

If we are prepared to pay the computational cost of using stochastic, nonlinear inversion methods as described earlier then we can relax the requirement that we have a unique misfit minimum since, in principle, multiple minima can be found and explored during the inversion and the true uncertainty can be assessed. In such cases, we might vary the survey design such that a measure of total expected information is maximized (Curtis and Spencer, 1999). However, this generally incurs the highest computational cost of any method proposed in this chapter. For geophysical problems with weak prior information about the model that we wish to estimate, this method is unlikely to be possible other than for low-dimensional problems [$P \sim 10$ in Eq. (17)].

6. Tomographic Applications

Tomography has been applied to many problems at length scales ranging from centimetres to the size of the Earth. There is too little space here to give an overview of all of these, so in the rest of this chapter we will focus on continental and cross-well scale tomography. We will show some examples that illustrate how the theory presented in this chapter has been applied, and how the results may be related to tectonically derived Earth structures.

6.1 Surface Wave Inversion Using the Born Approximation

Although traditionally the Born approximation has been used mostly to analyse reflection data (energy scattered from sharp

velocity discontinuities), it can also be used for the analysis of transmission data since it accounts for the complete first-order perturbation of the data by changes in the model. However, it is true that the domain of applicability is larger for reflection data than for transmission data. There is a simple physical reason for this. Suppose the velocity is perturbed with a small perturbation of say 1%. In general the reflected waves will be of the same order of magnitude; they will be around 1% of the incident wave-field and are therefore very weak. Suppose a transmitted wave experiences this velocity perturbation of 1% over 100 wavelengths. This leads to a phase shift of a complete cycle. This is no longer a small perturbation of the wave field so linearised theory will not be applicable.

For surface waves in global seismology the wavelength is fairly large. For example, a Rayleigh wave with a period of 75 sec has a wavelength of about 300 km. This means that these waves propagate over a limited number of wavelengths when they are used for continental-scale inversions. It is for this reason that these waves can be analysed using the Born approximation. A description of this method of analysis, the linearised inversion, and a number of numerical examples is given by Snieder (1988a). This technique has been applied to infer the shear-velocity structure under Europe and the Mediterranean by Snieder (1988b) and under North America by Alsina *et al.* (1996). Shear-velocity perturbations from the latter study in three layers with depths between 25 and 300 km is shown in Color Plate 21(b). Red colours map slow velocities that may indicate high temperature and green colours map high velocities corresponding to low temperature. Note, though, that the identification of velocity anomalies with temperature perturbations should be treated with care. Apart from temperature perturbations the seismic velocity is also affected by variations in composition, the presence of volatiles, such as water, and possibly also pressure. A tectonic interpretation of this model is given by Alsina *et al.* (1996). Images such as this make it possible to see “snaphosts” of plate tectonics in action.

6.2 Body and Surface Wave Comparisons

It was shown earlier that linearizing approximations need to be made both for the estimation and assessment of tomographic models. In general we do not know how nonlinear these tomographic problems are. However, whatever errors are committed by linearisation, we would not expect them to be the same errors in different studies using independent data and different data types. Hence, agreement or disagreement between such studies may be a reasonable indicator of the solution quality.

In continental and global-scale seismology, models have been produced using surface waves (e.g., Trampert and Woodhouse, 1995, 1996; Ekström *et al.*, 1997; Ritzwoller and Levshin, 1998; Curtis *et al.*, 1997; Lee and Nolet, 1997; Laske and Masters, 1998), normal modes (Woodhouse

and Dziewonski, 1984), and body waves (Robertson and Woodhouse, 1995; van der Hilst *et al.*, 1997; Bijwaard and Spakman, 2000). However, it was not until recently that these models began to look alike (e.g., Ritzwoller and Lavelle, 1995). Before this time, normal mode and most surface-wave models tended to be of very low lateral resolution, whereas body-wave models had very high resolution in some areas of the mantle and around seismically active zones in the lithosphere but very poor resolution elsewhere. Hence, there was no general agreement between the model structures found and it was not clear that the solutions found were really the only such structures that would fit the data.

More recently, surface-wave studies have produced models of continental structure with lateral resolution comparable to that of body-wave models. Color Plate 21(c) shows a comparison of 40 sec period, fundamental mode Rayleigh-wave phase velocity of Curtis *et al.* (1997) and a slice through the body wave P -velocity model of Bijwaard and Spakman (2000) at 53 km depth. To understand the phase-velocity model it is necessary to examine Figure 5 which shows the sensitivity of Rayleigh phase velocities to shear velocity at different depths in the Earth [these are the (normalised) kernels $K_\beta(z)$ in Eq. (16)]. Although P velocity and density also effect the phase velocity, shear velocity has a greater influence, hence these kernels show the dominant sensitivity.

FIGURE 5 Sensitivity of fundamental mode Rayleigh-wave phase velocity to shear velocity variations at depth.

Equation 16 shows that phase velocity anomalies at any point on the Earth's surface are averages of shear velocity anomalies over depth, weighted by these kernels. Hence, the 40 sec period Rayleigh wave is most sensitive to shear velocity anomalies in the depth range 40–100 km with peak sensitivity around 55 km. It makes sense, then, to compare this with the P -velocity model of Bijwaard and Spakman (2000) around 55 km depth: if P and S anomalies are correlated (if they are due to the same Earth structures) then the anomalies should exhibit similar patterns.

Despite the approximations made in the above argument, several features common to both models in Color Plate 21(c) are immediately obvious. The low velocity anomaly running from the Aegean, through the Caucasus and North Iran to the Pamir and Tien Shan north of Tibet is visible in both studies. Low velocities exist beneath central Tibet in both studies, as detected in previous studies using various data types (Romanowicz, 1982; Molnar and Chen, 1984; Curtis and Woodhouse, 1997). Also, the high velocities of the Northwest Indian subcontinent are visible and extend beneath the west-central Himalayan arc in both studies. India is actively subducting beneath the Tibetan plateau but there is still a debate about how far north the subducted plate extends. Both of these studies would suggest that the answer is almost 0 km in the east, increasing to approximately the width of the Karakoram mountain chain in the west, at least around 55 km depth.

7. New Developments and Future Research

Tomographic models using body-wave and surface-wave data now appear to attain comparable resolution within some volumes of the Earth, but their sensitivity to aspects of Earth structure are tremendously different (Figs. 1 and 5). In this sense the two data types are complementary: for example, body wave models tend to have low resolution within much of the Earth's lithosphere but higher resolution in the mantle, whereas fundamental mode surface waves provide better resolution of the lithosphere but very poor resolution of the deeper mantle. Hence, some research effort is currently being spent trying to create tomographic models consistent with both data types simultaneously.

This is just one example of how a new data type can be used to compensate for deficiencies of our current data types. Such strategies would seem to be the most efficient way to add constraints to any current model, since it is often the case that it is impossible to compensate for these deficiencies simply by adding extra data of the same type. (For example, Fig. 5 shows that one could add any number of fundamental mode surface wave observations at periods lower than 40 sec and never be able to constrain the mantle at 400 km depth.) The natural extension to this is to include all possible data types, and

recently a Bayesian framework to enable this was presented by Bosch (1999).

Some of the main issues highlighted above were the deficiencies of linearised inversion schemes. Clearly, to remove problems associated with this it is necessary to use nonlinear schemes that explore much more of the misfit surface than just a single misfit minimum. However, for tomographic problems this is still computationally intractable (Curtis and Lomax, 2001). Indeed, it is only recently that iterated linearised inversion has been achieved in global tomography, and even this has only been attempted from a single initial reference model (Bijwaard and Spakman, 2000). Linearised inversion from different reference models and introducing fully nonlinear inversion are areas of future research that will surely follow as computer power increases and more efficient methodologies are found.

Two important areas of tomography that we have not had space to discuss in detail are industrial tomography and seismic anisotropy. Seismic anisotropy is the name used to describe the variation in seismic velocity for waves either travelling or oscillating in different directions. Many studies have been carried out to attempt to constrain anisotropy within the Earth (e.g., Nataf *et al.*, 1986; Montagner and Nataf, 1988; Laske and Masters, 1998), but the data geometries available using earthquake data do not always enable detailed anisotropic structure to be resolved distinctly from the isotropic structure across much of the Earth. Studies in which seismic anisotropy is most likely to be best constrained occur in industrial geophysics where surveys can be designed using the methods presented earlier to provide extremely dense data geometries that are fit specifically for this purpose. Detecting anisotropy is important for hydrocarbon production and in selecting sites for waste disposal since it tends to indicate the orientation of the prevalent fracture field. Such fracture networks produce anisotropic permeability and hence can dramatically change either the optimal network of wells required to drain a reservoir, or our estimates of the directions in which waste-infected groundwater might flow. For these reasons a great deal of industrial research is currently directed toward developing new methods for anisotropy detection.

Color Plate 22 shows an example of the isotropic components of seismic velocity found from cross-well tomography at a site in Europe (see Miller and Chapman, 1991; Miller and Costa, 1992). The upper plot was obtained when only isotropic velocity components were included in model vector **m** in Eq. (17); the lower plot was obtained when **m** included both isotropic and anisotropic velocity components. The Earth structure is clearly fairly constant horizontally between the wells, but the left-hand tomogram shows a superimposed “X” structure. This is characteristic of cases where the data were generated by wave propagation through an anisotropic medium but where the model basis functions [Eq. (17)] cannot represent this anisotropy. The cross appears by spectral leakage of the anisotropic structure into the isotropic model basis

components (Section 4). This effect is removed by using a more appropriate choice of basis functions (Color Plate 22, lower plot) that includes the anisotropy of the medium.

It has been impossible to describe all the methods now used for tomographic applications, and there are many more research areas being investigated than the few mentioned here. We have tried to cover those techniques that are common in, or may be useful for, regional or global seismology. For techniques and applications not covered here, we refer the reader to Aki and Richards (1980) or Dahlen and Tromp (1998).

1. Introduction and Historical Review

Seismologists have been investigating the elastic properties of the Earth's deep interior for more than a century, but observations of seismic anisotropy are quite recent. The first observational evidence can be traced back to the early 1950s when, in connection with the development of seismic exploration techniques, it was found that the velocity of P waves could depend on their incidence angle in layered sediments. It soon became evident, however, that the amount of anisotropy that is required should not substantially affect the exploration techniques in use at that time (Krey and Helbig, 1956). In the subcrustal lithosphere, the first reports of seismic anisotropy were made in the early 1960s with observations of both apparent incompatibilities between the Love- and Rayleigh-wave velocities and azimuthal variations of Pn velocities. These two kinds of observations were independently attributed to the effect of partial melt in the upper mantle (e.g., McEvilly, 1964; Aki, 1968) and to preferred orientation of olivine crystals beneath the oceanic crust (Hess, 1964). For years, these earliest findings were considered more as marginal facts than signs of a situation that could prevail in many parts of the Earth.

Furthermore, many scientists have expressed doubts during the past 30 y on the necessity of invoking anisotropy to explain some of the reported observations. The earliest Love-wave observations were, for example, considered as contaminated by higher modes and of no value with regard to the question of seismic anisotropy (James, 1971). Other authors pointed out the problem of a trade-off between anisotropy and lateral heterogeneities (e.g., Levshin and Ratnikova, 1984).

The number of studies dealing with seismic anisotropy has dramatically increased during the past 10 y. It is out of the scope of the present chapter to present an exhaustive review of the subject. The literature published before 1990 has been reviewed by Babuska and Cara (1991). Since then, mantle anisotropy has been reviewed by Silver (1996), Montagner (1998), and Savage (1999) and a monograph dedicated to various theoretical aspects of seismic anisotropy (Helbig, 1994) is useful in the field of seismic exploration techniques.

In the present chapter, we mainly focus our attention on the seismological aspects of the subject and on several results linking the observations of seismic anisotropy to dynamic processes acting in the Earth. Due to the very rapid growth of literature on the subject, it was not possible to list all the recent publications. Only a selected list of references is given, and questions related to mineral physics and rock properties are only marginally addressed.

Let us first recall that the theory of elasticity in homogeneous anisotropic media was already well advanced by the mid-19th century, after the works of Louis Cauchy and George Green. Elasticity of crystals was thoroughly studied later on, and their anisotropic properties have spread light on the 19th century controversy concerning the number of elastic constants to be considered in a general anisotropic solid (e.g., Love, 1944). It is also worthwhile to recall that the development of the theory of elasticity had been intimately linked with research on the propagation of light. The then broadly accepted concept of immaterial "ether" was the ground on which the theory of propagation of the transversely polarized optical waves was developed, and the properties of elastic waves in solids served as a guideline. Finally, let us note that the term "anisotropy" was not adopted in the former English literature. Instead, Kelvin (1904) proposed the word *aelotropy*: "I see the Germans have adopted the term anisotropy. If we used this in English we should have to say, *An anisotropic solid is not an isotropic solid*; this jangle between the prefix an (privative) and the article an, if nothing else, would prevent us from adopting that method of distinguishing a nonisotropic solid from an isotropic solid."

Elastic anisotropy of homogeneous media is a good start to study the propagation of seismic waves, but more theoretical developments are required to address the question of wave propagation in the Earth. The effects of both inhomogeneities and anisotropy of the medium have to be taken into account. A first step is to consider elastic models with depth-varying properties. At a plane discontinuity between two homogeneous anisotropic media, because of the three possible elastic waves with orthogonal polarizations, reflection and refraction of

a plane wave give birth to three reflected and three refracted waves (e.g., Musgrave, 1960). Transverse isotropy, i.e., symmetry about a fixed axis, is frequently used as an approximation for realistic situations in the Earth. Love's notations for the five elastic parameters of transversely isotropic media (Love, 1944) are broadly used in surface-wave and normal-mode seismology (e.g., Anderson, 1961; Takeuchi and Saito, 1972; Dziewonski and Anderson, 1981). Other terms for transverse isotropy are "radial anisotropy" or "polarization anisotropy" (i.e., differences between SH and SV velocities). For obvious reasons of symmetry, a transversely isotropic medium with invariant properties about the vertical direction is also the only one that is compatible with a spherical symmetry. Travel times in a transversely isotropic spherical model were given by Woodhouse (1981), using the asymptotic behavior of normal modes.

Backus (1962) looked at the important properties of media made of thin isotropic layers with different elastic properties. At long wavelengths, he showed that a stack of parallel plane layers is transversely isotropic with its symmetry axis perpendicular to the plane of the layers. Thomsen (1986) studied the case of weak anisotropy in such transversely isotropic media about a vertical axis of symmetry. He introduced several notations commonly used in the field of exploration geophysics. Within a seismic wavelength, there is thus no way to distinguish between intrinsic anisotropy and anisotropy induced by a thin layering of materials with different rigidities or by small nonspherical isotropic heterogeneities. This is why the term "seismic anisotropy" is well adapted to a description of the material properties at the scale of a seismic wavelength. Note that the seismic properties of materials exhibiting a shape-induced anisotropy, also called "shape preferred orientation" anisotropy (SPO), play an important role in the crust. In addition to the problem of layered sediments, it soon became evident that distributions of fluid-filled cracks in the crust (Crampin, 1984) could be a major cause of SPO anisotropy. Again, transversely isotropic models, but with horizontal axis of symmetry, became a standard simplified model to investigate crack-induced anisotropy in the crust.

Leaving the field of transversely isotropic structures, let us recall that Stoneley (1963) developed the theory of surface waves in orthorhombic media. Crampin (1970) did the first calculation of surface-wave phase velocities in flat-layered anisotropic media, showing all peculiarities of anisotropic surface waves, including their anomalous polarizations. Backus (1965) used perturbation theory to estimate the azimuthal variation of velocity in refracted Pn waves for weakly anisotropic media. In doing so, he opened the way to many theoretical studies of weakly anisotropic media. Smith and Dahlen (1975) and Montagner and Nataf (1986) extended the perturbation theory to surface waves and developed useful tools for interpreting the Love- and Rayleigh-wave velocities in arbitrary anisotropic media. Properties of cracked media, assuming the long wavelengths approximation, have been

extensively studied by several authors (e.g., Hudson, 1980; Sayers, 1998).

Although the observational evidence for anisotropic behavior of seismic body waves in fully 3D structures has been rather weak until now, there is a clear need for developing the theory of seismic wave propagation in such structures, in particular for the purpose of seismic exploration techniques (e.g., Rüger, 1997). This raises considerable mathematical difficulties. The earliest theoretical developments of ray theory in 3D anisotropic media were summarized by Cerveny (1972). They made possible the computation of travel times and amplitudes in the high frequency limit. Numerical computations, however, are much more complicated than in isotropic media since an eigenvector-eigenvalue analysis of the Christoffel matrix has to be performed at each step of propagation along a ray. Two basic approaches have been followed to reduce the computer time: perturbation methods (e.g., Farra, 1989; Jech and Psencik, 1989; Chapman and Pratt, 1992) and factorization of the anisotropic media in homogeneous blocks (Cerveny, 1989; Farra, 1990). Together with various high-frequency asymptotic techniques (e.g., Garmany, 1988a,b), these approaches constitute a very active field of research in theoretical seismology. Among several recent studies related to body-wave theory in anisotropic media, Gajewski and Psencik (1990) applied the concept of dynamic ray tracing to compute vertical seismic profile (VSP) synthetics, Babich (1994) made a systematic study of the estimate of amplitudes on wavefronts, Grechka and Obolentseva (1993) looked at the shear-wave behavior near directions of singularity of the Christoffel matrix, and Bakker (1998) looked at the problem of phase shift at caustics. As an alternative to the high-frequency approximation of ray theory, Hung and Forsyth (1998) make use of parallel computing techniques to obtain complete synthetic seismograms in an oceanic inhomogeneous structure.

Finally, before closing this introduction, it should be noted that the way seismic waves attenuate along their propagation path may also depend on their direction of propagation. This seismic "attenuation anisotropy" may occur for example in media with preferred orientations of fluid-filled cracks (Peacock and Hudson, 1990). It may also be due to solid-state processes (e.g., Carcione and Cavallini, 1994).

2. Anomalies in Crustal-wave Polarization and Seismic Anisotropy

One of the most obvious manifestations of seismic anisotropy is shear-wave splitting. Ray theory predicts that a shear wave entering an anisotropic region is split into two shear waves polarized at right angles according to the local symmetry of the medium. In the high frequency limit of ray theory, the two split

waves are fully decoupled. They travel independently within the anisotropic region, and the time delay between the split waves varies along the ray, whereas their polarization follows the local symmetry of the anisotropic medium. Observations of split shear waves generated by crustal earthquakes recorded with short-period instruments at small distances from the source have been accumulated during the past 20 y. Interpretation of these observations in terms of alignment of fluid-filled cracks is the most commonly adopted explanation (Crampin, 1978), although there are situations where preferred orientation of minerals may also be put forward (e.g., Kern and Wenk, 1990). When interpreting observations of split shear waves in terms of anisotropic structures, let us note that Coates and Chapman (1990) have shown that great care must be taken if the time delay between the split shear waves is small. They have shown that the high-frequency limit of ray theory may then lead to misleading results when ignoring the coupling between the split shear waves.

In connection with dilatancy theory, Gupta (1973) suggested that observation of temporal changes in *S*-wave splitting might contribute to short-term earthquake prediction. Crampin (1978) developed this idea further. His model called "Extensive Dilatancy Anisotropy" (EDA) closely links the direction of maximum horizontal compressive stress with the direction of polarization of fast shear waves propagating vertically. Considering that crack-induced anisotropy could be a widespread phenomenon, he proposed that the observed temporal changes in *S*-wave splitting might be used as earthquake precursors. Indeed, there are several observations made in tectonically active regions where fast shear-wave polarizations are parallel to the maximum horizontal compressive stress, as in Imperial Valley, California (Zollo and Bernard, 1989), or in the Gulf of Corinth, Greece (Bouin *et al.*, 1996). There are other situations, however, where this is not the case. Paleostress might then better correlate with the fast shear-wave polarization direction (Blenkinsop, 1990; Aster and Shearer, 1992; Diagne *et al.*, 1996). If the reality of seismic anisotropy in the crystalline crust seems well established, observed time changes between the split shear waves have been much more controversial during the past decade. The interest in such temporal variations of shear-wave splitting is such that many groups attempt to monitor them (e.g., Gao *et al.*, 1998; Crampin *et al.*, 1999).

Shear-wave splitting observations have been attributed to preferred orientation of fluid-filled cracks in geothermal fields (e.g., Evans *et al.*, 1995; Sachpazi and Hirn, 1991) and in a region of extensional tectonics in the Gulf of Corinth (Bouin *et al.*, 1996). In the upper crystalline crust, direct observations of *S*-wave splitting have been reported in the Kola deep continental well from VSP measurements (Diagne *et al.*, 1996). A shear-wave velocity anisotropy up to 4.5% has been found there together with a direction of propagation of fast *S* waves parallel to the direction of the

maximum compressive paleostress. Diagne *et al.* (1996) favor preferred alignment of hornblende minerals instead of a distribution of cracks to explain their observations. In the deep continental crust, an azimuthal variation of shear-wave velocities has also been reported from two orthogonal refraction profiles in Norway (Mjelde *et al.*, 1995), and shear-wave splitting was observed from teleseismic *P* waves converted into *S* waves at the Moho discontinuity in different tectonic settings [e.g., Herquel *et al.* (1995) in Tibet; Levin and Park (1997) in the Ural Mountains].

In addition, in many circumstances the deep seismic sounding profiles performed in the continental crust have revealed a high reflectivity of fault zones within the crystalline basement that is much larger than would be expected from any plausible velocity contrast between both sides of the fault. Anisotropy of mylonite could explain such a strong reflectivity of some faults by preferred orientation of phyllosilicates, and possibly by laminar structure of alternating high- and low-velocity layers in the fault zone (Jones and Nur, 1984). These authors estimated the thickness of the reflective zone to be 100–150 m in the case of the Wind River and the Pacific Creek thrust.

Finally, let us emphasize that monitoring seismic anisotropy by shear-wave splitting measurements in sedimentary layers is a very challenging prospect for exploration geophysicists (e.g., Clief *et al.*, 1991). Crampin (1984) proposed that the EDA model could also serve as a guide to explain *S*-wave splitting observations as due to preferred orientation of fluid-filled cracks for reservoir definition.

3. Seismic Anisotropy in the Upper Mantle: Lithosphere, Asthenosphere or Both?

If crack-induced anisotropy is probably an important cause of seismic anisotropy in the crust, lattice-preferred orientation (LPO) of olivine in peridotites is generally considered as the major cause of upper mantle anisotropy (e.g., Nicolas and Christensen, 1987). As stated by Silver (1996), two types of observation have played a major role in detecting upper-mantle anisotropy: observations linked with the polarization of seismic waves, either *S* waves or surface waves, and observations of local variation of the wave velocity with the direction of propagation. Incompatibility between the observed Love- and Rayleigh-wave velocities belongs to the former type of observations. This so-called Love–Rayleigh wave discrepancy played an important role in the earliest studies of upper-mantle anisotropy. Azimuthal variations of *P_n* velocity in the subcrustal oceanic lithosphere belongs to the second type of observations. They were interpreted as due to preferred orientation of olivine crystals in the accretionary process of the oceanic lithosphere (Francis, 1969).

Kind *et al.* (1985) and Silver and Chan (1988) reported observations of transverse components of *SKS* waves on horizontal records, whereas no such transverse motion should be observed in a spherical isotropic Earth. They attributed this anomaly to shear-wave splitting of *SKS* waves in the upper mantle. Since then, thanks to the deployment of broadband seismometers and to the generalization of digital recording (e.g., Vinnik *et al.*, 1989a), the number of such observations has increased dramatically on all continents (for a review see Silver, 1996, and Color Plate 23, and Savage, 1999). In the last 10 y, an impressive amount of observations of shear-wave splitting attributed to upper mantle anisotropy has been reported in the literature. Several attempts have also been made to use other mantle shear waves, either *ScS* (Fukao, 1984; Ansel and Nataf, 1989), direct mantle *S* waves, or *Ps* waves converted at the discontinuities of the upper mantle seismic transition zone (e.g., Vinnik and Montagner, 1996).

The former models used to explain the *SKS* splitting observations in continental regions were rather simple, being made of an olivine-rich homogeneous layer 100–300 km thick. In this simple model, which fits many observations, the polarization of the fast shear wave gives us the direction of preferred orientation of the olivine *a* axes in the horizontal plane, and the time delay between the split shear waves gives us an estimation of the thickness of the layer assuming a reasonable LPO anisotropy in the upper mantle. The two main reasons why a model of lithospheric anisotropy was developed (Silver and Chan, 1988) are: (1) the clear correlation between the observed directions of shear-wave splitting and the trends in surface tectonics; and (2) the fact that there was no evidence for a deeper cause of shear-wave splitting in the lower mantle. Indeed, very weak anisotropy is expected in the deep mantle if one excludes the *D''* layer in its lowermost part (Meade *et al.*, 1995). It also has been quite obvious that small-scale lateral variations of both the symmetry directions and amplitudes of seismic anisotropy were strongly in favor of a lithospheric origin.

Independently of *SKS* studies, it has been recognized for a long time that 3D isotropic models of the mantle were unlikely to explain the variations of *P*-wave travel-time residuals observed at a given station for rays with different azimuths and incidence angles (Dziewonski and Anderson, 1983). It was also soon recognized that the amount of seismic velocity variations could be as large as the effect of anisotropy in upper-mantle materials (e.g., Anderson, 1989). The pattern of observed *P*-wave residuals in central Europe has been interpreted in terms of dipping anisotropic bodies in the lithosphere, possibly paleosubducted plates (Babuska *et al.*, 1984). Plomerova *et al.* (1996) made a joint interpretation of *P*-wave residuals and *SKS* splitting observations in Fennoscandia and the western United States. The fact that a single LPO anisotropic model with dipping anisotropic structures may explain both sets of data gives a firm basis for the

interpretation of upper mantle anisotropy as frozen in the lithosphere beneath continents.

The question of the precise location of the seismic anisotropy revealed by *SKS* splitting observations, however, gave rise to a controversy that is not yet closed. Indeed, because vertically incident rays lack any depth resolution, only indirect arguments, such as correlations with the local geology or with the directions of present plate motions, have been used in the former debate. A recent re-examination of this question by Kubo and Hiramatsu (1998) shows that *SKS* splitting data correlate with the directions of the present absolute plate motions, which is in favor of an asthenospheric origin, but for plate velocities larger than 1.4 cm y^{-1} only. For slower plates, no correlation is found and the observed *SKS* splitting observations are more likely due to frozen-in anisotropy in the lithosphere. Unfortunately, the use of *P*-wave residual data does not help a lot in this debate because the teleseismic rays follow subvertical paths in the upper mantle and azimuthal variation of *P*-wave velocities have little effect on their travel times. Surface waves are more useful since a rather good depth resolution both in polarization anisotropy and azimuthal anisotropy may be achieved in the upper mantle. Horizontal resolution, however, is much poorer than in *SKS* studies.

Inversion of global normal-mode data also has provided evidence for seismic anisotropy in the upper mantle for a long time. In the broadly used global model PREM (Dziewonski and Anderson, 1981), a few percent polarization anisotropy is required in the upper 220 km. In regional studies, the former interpretation of the observed discrepancies between the Love- and Rayleigh-wave velocities were made in terms of flat horizontal pockets of partial melts (e.g., Aki; 1968; Schlue and Knopoff, 1976). It has been conceded later that they could also be interpreted in terms of LPO anisotropy without invoking partial melt. Both mechanisms can predict the observed discrepancies between the Love- and Rayleigh-wave velocities, but only LPO anisotropy gives us a reasonable explanation for the *SKS* splitting. In the former studies, only fundamental-mode surface waves were used, lacking in depth resolution, and the question of the depth extent of anisotropy was not easy to address. For example, Schlue and Knopoff (1976) favored an asthenospheric origin for the polarization anisotropy observed in the Pacific, whereas Mitchell and Yu (1980) favored the lithosphere. Forsyth (1975) was the first to use higher-mode surface waves to investigate the upper-mantle structure beneath the Pacific with better depth resolution. He was also the first to resolve the azimuthal variations of Rayleigh-wave velocities and to interpret them in terms of LPO anisotropy. More recently, using higher modes of Love and Rayleigh waves, Cara and L  v  que (1988) found a clear anisotropic layer extending to at least 200 km beneath the Pacific Ocean, extending thus well below the lithosphere. Nishimura and Forsyth (1989), inverting a large set of data related to the Pacific Ocean, found that seismic anisotropy is not confined to a 100 km thick lithosphere but extends well

below, within the shear-wave low-velocity zone in the asthenosphere. A model explaining seismic anisotropy of the asthenosphere by finite deformation of upper mantle materials under resistive drag of the sublithospheric mantle has been developed recently by Tommasi *et al.* (1996). It gives a solid basis for the interpretation of the seismic anisotropy observed in the asthenosphere beneath the Pacific.

More powerful tools can now be used to determine the depth extent and lateral variation of seismic anisotropy in the upper mantle. Waveform inversion techniques allow us to interpret the whole shape of a seismogram in terms of depth-varying anisotropic structures. They automatically include the higher-mode content of the surface-wave signal and exploit their great potential for increasing depth resolution. Inverting a set of high quality broadband surface-wave records for many sources and receivers, Lévêque *et al.* (1998) obtained a 3D anisotropic model of the Indian Ocean and its surrounding areas with an unprecedented lateral and vertical resolution. The azimuthal variation of *SV* waves was in particular well resolved on a horizontal scale of 1000 km. The direction of fast *SV* velocities and the directions of the present absolute motion of the plates are well correlated at depth. The correlation breaks down in the lithosphere, above 100 km beneath the Indian Ocean and above 200 km beneath Australia, the only continental region well constrained by the data used in this study. Color Plate 24 shows the map of *SV*-wave velocities and their azimuthal anisotropy at 150 and 200 km. Beneath Australia, a clear rotation of the fast direction of propagation of *SV* waves takes place between the 150 and 200 km depths, with fast *SV* waves in the east–west direction in the lithosphere and fast *SV* waves in a direction parallel to the south–north motion of the Australian plate at 200 km. Using broadband data recorded during the SKIPPY experiment in Australia, Debayle (1999) confirmed this overall rotation pattern beneath central and eastern Australia at about 150 km depth.

In an independent study, Girardin and Farra (1998) have interpreted SKS splitting observations made in Canberra with a two-layer anisotropic model. A similar 90° rotation from a north–south to an east–west direction is found for the polarization of the fast shear waves when passing from the lower asthenospheric layer to the upper lithospheric layer.

All these findings suggest that beneath central and eastern Australia the fast direction of propagation of *SV* waves within the lithosphere could be dominantly oriented east–west, while it could become north–south below. According to the mechanism proposed by Tommasi *et al.* (1996) for the Pacific, a plausible explanation is that the present shearing strain below a 150 km-thick continental lithosphere could cause an LPO anisotropy in an olivine-rich upper mantle. It is interesting to recall that a similar hypothesis had been proposed by Leven *et al.* (1981) to explain the abnormally high *P* velocities observed at about 200–250 km depth beneath northern Australia.

Taking into account all kinds of arguments exchanged during the past 20 y on the location of upper mantle anisotropy, it now seems quite obvious that both frozen-in anisotropy in the lithosphere and dynamic deformation of the root of the lithosphere and the upper part of the asthenosphere are involved. The role of SPO anisotropy due to partial melts of the upper mantle, once a rather popular explanation, does not seem necessary to explain most of the presently available observations, except perhaps beneath active spreading centers. Using data from broadband ocean bottom receivers, Webb and Forsyth (1998), for example, found very low shear-wave velocities down to 100 km depth beneath the East Pacific Rise together with incompatibility between the Love- and Rayleigh-wave velocities. Because *S*-wave splitting observations have also been made on the ocean floor during this experiment (Wolfe and Solomon, 1998), both LPO anisotropy, with olivine *a* axes parallel to the spreading direction, and aligned melt pockets in horizontal directions may be required to fit the data.

At a smaller regional scale, several authors have shown that upper mantle seismic anisotropy is also required in subduction zones. The questions whether the upper lithosphere, the asthenospheric wedge above the subducting slab, or the slab itself is anisotropic has been debated during the past 20 y (e.g., Savage, 1999). Ando and Ishikawa (1980), and Ando *et al.* (1983) have observed local *S*-waves splitting in Japan for intermediate and deep earthquakes. They interpreted this observation as being due to the upper mantle wedge between the surface and the subducting slab, invoking lateral variations over horizontal distances of 50–100 km to explain the changing pattern of their *S*-wave splitting observations. Using *ScS* waves reflected at the core–mantle boundary, Fukao (1984) observed a more homogeneous pattern for the directions of polarization of the fast *S* waves. As these directions are roughly parallel to the plate convergence, he suggested that the cause of the splitting might be preferred orientation of olivine crystals *a* axes within the slab. Since then numerous *S*-wave splitting observations have been made in subduction zones. Many show fast directions of polarization parallel to the trenches (e.g., Silver and Chan, 1991). Fisher and Yang (1994) looked at differential splitting observations between teleseismic *sS* and *S* phases coming from intermediate and deep earthquakes in the Kurils–Kamchatka. Completing this information by local *S*-wave observations, they infer the anisotropy pattern of both the upper mantle wedge and the overriding lithospheric plate. They found a rather complex pattern, invoking both asthenospheric flow in the wedge above the subducted slab and deformation of the upper lithospheric plate in the back-arc area.

Fouch and Fischer (1996) concluded that the variability of *S*-wave splitting observations in the different subduction zones could be explained by preferred orientation of olivine crystals in both the upper lithosphere and the asthenospheric flow above the subducted slab. Seismic anisotropy in the

subduction zone could thus be governed by the local conditions of the plate convergence and the tectonic spreading and shearing of the lithosphere in the back-arc area.

4. The Deep Mantle and Core

If the presence of seismic anisotropy in the upper mantle is supported by many seismological investigations, there is presently no evidence of seismic anisotropy in the bulk of the lower mantle (e.g., Meade *et al.*, 1995). Only its upper and lower parts exhibit signs of anisotropy. In their study of subduction zones of the Pacific, Fouch and Fischer (1996) concluded that anisotropy of the lower mantle is very unlikely. Quite convincingly, they compare splitting observations of local *S* waves coming from deep earthquakes in subducted slabs and *SKS* waves coming from the core. They show that deep lower mantle anisotropy can be ruled out, except if anisotropy cancels out along the long ray path between the core–mantle boundary and the upper-mantle transition zone.

At a very large scale, evidence for a weak polarization anisotropy between the upper and lower mantle has been advocated by Montagner and Kennett (1996) from a global inversion of normal mode and body-wave data. According to Karato (1998), who reviewed the different data related to seismic anisotropy in the deep mantle and explored their geodynamical significance on the basis of mineral physics, Montagner and Kennett's (1996) results with a reverse *SH/SV* anisotropy above and below the 660 km discontinuity might be interpreted as due to horizontal shearing in the lower part of the transition region. This would support a partially two-layered convection pattern of the mantle with horizontal shearing between the upper and lower mantle. However, Kiefer and Stixrude (1997), computing values of the elastic constants of Mg_2SiO_4 spinel at high pressure, found a predicted anisotropy for *P* and *S* waves which is not in agreement with the radial anisotropy found in the depth range 410–600 km by Montagner and Kennett (1996). Looking now either at spherical harmonic expansions of global normal mode data (Montagner and Tanimoto, 1991) or at several subduction zones (Fouch and Fischer, 1996), it became evident that if seismic anisotropy is required in the transition zone, large lateral variations do occur there. Anisotropy is for example not required in the transition zone beneath the Izu Bonin but it is required beneath the southern Kurils (Fouch and Fischer, 1996). Interestingly, these lateral variations could be coupled with the mechanical barrier resisting the downward motion of the plates at 600 km depth (Karato, 1998).

Further investigation of the anisotropic properties of the upper mantle transition region, together with their lateral variations, is certainly needed to better understand the dynamics of this important boundary layer of the Earth.

The possibility of radial anisotropy at the bottom of the mantle, within the *D''* boundary layer, was mentioned by Doornbos *et al.* (1985). Investigating polarization of diffracted *SV* waves, Vinnik *et al.* (1989b) suggested that azimuthal anisotropy could also take place in *D''* layer. The fact that *SH* waves traveling horizontally at the core–mantle boundary are generally faster than *SV* waves has been proposed by several authors (e.g., Maupin, 1994). Pulliam and Sen (1998), however, have found *SV* waves are faster than *SH* beneath the central Pacific, a zone of ultralow seismic velocities (Williams and Garnero, 1996). In fact, *D''* appears as a strongly inhomogeneous boundary layer, both for the seismic velocities and for seismic anisotropy. Due to the strong velocity reduction observed in the superswell region beneath the Pacific, a possibility of partial melt is not excluded (Williams and Garnero, 1996). The *D''* boundary layer, a region of the Earth which is unevenly sampled by seismic rays, might thus be a complex zone where LPO of both perovskite and magnetowustite could take place together with other SPO anisotropy involving partial melts within a dynamic shearing strain (Karato, 1998; Ritsema *et al.*, 1998).

In the inner core of the Earth, two independent sets of data have led seismologists to consider that it could be strongly anisotropic with hexagonal symmetry and a symmetry axis close to the rotation axis of the Earth. The first set of data is *PKIKP* travel times. Morelli *et al.* (1986) corrected the observed *PKP(DF)* travel times from the effects of the upper-mantle and core–mantle velocity anomalies known at that time. A strong zonal character appeared in the residual inner-core travel times, attaining about 2 sec. Vertically propagating *PKIKP* waves were found to be faster along the rotation axis of the Earth than in the equatorial plane. As no plausible heterogeneity could explain these observations, Morelli *et al.* (1986) proposed that the inner core might be anisotropic with a cylindrical symmetry parallel to the Earth's axis of rotation. A similar observation was made by Cormier and Choy (1986) from the variation in differential travel times between *PKP(DF)* and *PKP(BC)*. In that case no correction for lateral variation of mantle *P* velocities was applied to the data since the two rays have rather close paths in the mantle. The second set of data comes from the analysis of split core modes in the free oscillation spectra of the Earth (Woodhouse *et al.*, 1986). These latter data need 25-km high undulations of the inner-core boundary and large heterogeneities near the upper part of the inner core to be explained by isotropic models (Giardini *et al.*, 1987). A homogeneous spherical model including a hexagonal anisotropy of the inner core with the axis of symmetry coincident with the Earth's rotation axis is an alternative model that fits the splitting observations as well.

The earlier findings on inner-core anisotropy have been confirmed since then by several authors using both differential travel time analysis (e.g., Shearer and Toy, 1991)

and normal-mode splitting observations (Tromp, 1993). Furthermore, not only has the inner-core anisotropy been broadly accepted during recent years, but the fact that both its axis of symmetry may be tilted with respect to the Earth's rotation axis (Creager, 1992) and that the $PKP(BC)$ - $PKP(DF)$ travel times may have changed during the past 20 y have led Song and Richards (1996) to propose that the inner core could rotate with respect to the Earth's mantle. Souriau *et al.* (1997) critically examined these results. They concluded that even if differential rotation of the inner core could not be ruled out, they doubted that it actually had been detected. Whatever the rotation of the inner core is, the former image of a homogeneous anisotropic inner core with hexagonal symmetry about the Earth's rotation axis appears now as an oversimplified view. Observations of heterogeneities in the inner core (Su and Dziewonski, 1995), if not a tilted axis of symmetry, are now quite broadly accepted. The search for the cause of seismic anisotropy in the inner core is a new challenging problem in solid Earth physics. Weber and Machetel (1992) considered that the inner core can be convective and that dynamically induced anisotropy in high-pressure iron phase is possible. Summarizing our present state of knowledge of the solid-state physics of the inner core, Bergmann (1998) addressed the problem of iron grain size. Within a range between 5 mm and 2000 km, he favored a grain size of the order of 100 m.

Another intriguing manifestation of inner-core anisotropy is the variation of seismic attenuation with the inclination of the $PKIKP$ rays with respect to the axis of rotation of the Earth. Souriau and Romanowicz (1996) reported a clear variation of $PKP(DF)/PKP(BC)$ amplitude ratios which are about five times smaller for paths close to the rotation axis of the Earth than for nearly equatorial paths. They interpreted this strong amplitude variation as most likely due to anisotropy in seismic attenuation within the inner core.

5. Trade-off between Anisotropy and Heterogeneities

As already stated, evidence for seismic anisotropy may come either from local variation of seismic velocities with respect to the direction of propagation, or from anomalies linked with their polarization. The former type of observation is generally considered as less robust since correction for velocity variations along the ray path is generally done before searching for its local angular variations. In fact, polarization of the waves may also be affected by heterogeneity of the structure. Tilted interfaces, for example, may generate waves propagating in three dimensions, and rays traveling off the source-receiver vertical plane could mimic anomalies in polarization. When using converted PS waves at seismic discontinuities, tilted interfaces may also produce transverse shear waves that can

be misinterpreted as due to anisotropy of the medium. For example, to avoid such a misinterpretation, Peng and Humphreys (1997), and Savage (1998) simultaneously determined the Moho dip and crustal anisotropy when inverting teleseismic receiver functions.

In surface-wave seismology, many effects can be attributed either to lateral heterogeneities of an isotropic structure or to anisotropic properties of the upper mantle. Levshin and Ratnikova (1984), for example, performed a numerical experiment with a laterally varying isotropic model made of two quarter-spaces in contact. Their results show that the Love- and Rayleigh-wave velocities are not compatible with a single laterally uniform structure. They suggested that it is not necessary to invoke anisotropy to interpret the Love-Rayleigh wave discrepancies that are so frequently observed, but that lateral variation of isotropic structures could also explain these observations. Babuska and Cara (1991) commented on this numerical experiment. They concluded that if such an effect is indeed possible, it requires strong enough lateral variations of structures so that non-linear effects may take place when passing from the local surface-wave velocities to the average velocity along the surface-wave path. Another example where isotropic heterogeneities and lateral variations of seismic anisotropy can equally explain observed anomalies in the seismic wavefield is given by Kobayashi and Nakanishi (1998). They report observations of secondary Love waves in Japan coming from converted Rayleigh waves beneath the Aleutian or Kuril trenches. Referring to a theoretical study of mode coupling effects by Yu and Park (1993), these authors conclude that the Rayleigh- to Love-wave conversion is most probably due to lateral variations of anisotropy in the upper mantle, but that laterally varying isotropic structures could nevertheless also produce the observed effects.

Much care must be taken when performing inversion of seismic data in terms of both 3D inhomogeneities and anisotropy. Ignoring either inhomogeneities along the wave path or anisotropy may lead to erroneous results. L  v  que *et al.* (1998), for example, carefully checked how an isotropic 3D structure could affect the azimuthal anisotropy of SV -wave velocities they have obtained from inversion of path-averaged surface-wave velocities. They concluded that there is a slight trade-off between the anisotropic pattern shown in Color Plate 24 and the 3D structure of the upper mantle, but the effect is small and does not alter the major trends in azimuthal variations of SV velocities shown in Color Plate 24.

Leaving the field of surface-wave seismology, it is of prime interest to look at the problem of teleseismic P -wave travel-time tomography, since most results published to date ignore the possibility that anisotropy may bias the results. To investigate this problem, Sobolev *et al.* (1999) performed several numerical experiments with realistic ray configurations and a plausible LPO anisotropy in the lithosphere and asthenosphere. Direct computations of P -wave

travel-time residuals are made for several laterally and vertically varying anisotropic structures. The synthetic residuals are then inverted using a 3D isotropic tomographic code. Several anisotropy-induced artifacts are clearly apparent in the results. Even if, in some ray configurations, the apparent pattern of the inverted seismic velocities seems not affected, the amplitude of the velocity variations is. Interpretations of the seismic tomography results in terms of mineral composition or temperature variations may thus be misleading if anisotropy is ignored. When dealing with travel-time inversion, there are other circumstances where remote heterogeneities or anisotropic bodies may affect the results of tomography. As an example, let us mention the study of the structures of the deep mantle and core by Garnero and Lay (1998). These authors pointed out that anisotropy in D'' could significantly affect the isotropic P -wave velocity structure of the outer core.

6. What's Next?

The above considerations show that, except in the bulk of the lower mantle and the outer core, seismic anisotropy cannot be ignored any longer in most seismological investigations. From the crust to the inner core of the Earth, lateral and vertical variation of seismic velocities may be closely linked with some level of seismic anisotropy in the structure. In turn, quantifying seismic anisotropy and its lateral and vertical variations in many parts of the Earth is a challenging research goal for seismologists. Many questions regarding the dynamics of the Earth can indeed be addressed by investigating the characteristics of seismic anisotropy. As an illustration, let us mention the question of the nature and thickness of the continental lithospheric roots, a major problem not yet satisfactorily solved. For example, Gaherty *et al.* (1999) advocate a deep continental root beneath western Australia whereas Debayle's (1999) results are in favor of a thinner lithosphere. As another example, Babuska *et al.* (1998) found a global variation of the SH/SV velocity ratio with regard to the age of continents. If this result is confirmed and its possible trade-off with the different lateral heterogeneities understood, it could convey new important information on the evolution of the continental lithosphere.

At greater depth, the question of anisotropy in the transition zone and its lateral variations is a clue to understanding the coupling between the upper and lower mantle (Karato, 1998). Finally, will we confirm that D'' is the only part of the lower mantle where seismic anisotropy is detectable? Will we be able to better constrain the lateral heterogeneities and seismic anisotropy within the inner core? After a decade where a wealth of new results has been gathered on seismic anisotropy in different parts of the Earth, it is clear that seismologists are faced with a lot of exciting questions to address in the

forthcoming years. Thanks to the deployment of broadband digital seismometers with a high-density coverage, we can be confident that much progress will be made on our knowledge of seismic anisotropy and on its connection with the Earth's dynamics.

1. Introduction

The purpose of this chapter is to provide a summary of the seismic velocity structure of the continental lithosphere, i.e., the crust and uppermost mantle. We define the crust as the outer layer of the Earth that is separated from the underlying mantle by the Mohorovičić discontinuity (Moho). We adopted the usual convention of defining the seismic Moho as the level in the Earth where the seismic compressional-wave (P -wave) velocity increases rapidly or gradually to a value greater than or equal to 7.6 km sec^{-1} (Steinhart, 1967), defined in the data by the so-called “ P_n ” phase (P -normal). Here we use the term uppermost mantle to refer to the 50–200+ km thick lithospheric mantle that forms the root of the continents and that is attached to the crust (i.e., moves with the continental plates).

This summary has been preceded by 90 y of intense scientific activity. Mohorovičić (1910) was the first to publish an

estimate for crustal thickness (54 km near Zagreb, Croatia), and to describe the seismically defined boundary between the crust and mantle that now bears his name (often shortened to “the Moho”). The fact that the oceanic crust is significantly thinner than continental crust (5 km versus about 40 km) was documented 40 y later (e.g., Hersey *et al.*, 1952). Numerous later studies demonstrated that the continental crust varies in thickness from about 15 km to greater than 70 km beneath the Tibet plateau. Jarchow and Thompson (1989) provide a useful summary of early crustal studies, and Table 1 provides additional references. We emphasize results from active-source seismic refraction profiles that provide detailed *P*-wave velocity information. The shear-wave (*S*-wave) structure of the crust and uppermost mantle, as determined by surface waves, is discussed, for example, by Ekström *et al.* (1997) and Ritzwoller *et al.* (1998).

2. Data and Methods of Analysis

The properties of the Earth's lithosphere are particularly well suited to measurements using seismological data due to the existence of the pronounced variations in seismic wave speeds both laterally and with depth. Beneath continents, the Moho is characterized by a more or less rapid increase of *P*- and *S*-velocities with depth. However, because *S*-waves travel more slowly than *P*-waves and therefore cannot be detected as first arrivals, they are often hidden in the coda of the *P*-waves. Thus, the study of *S*-waves for crustal research has been a limited, but rapidly growing, area of research, and a worldwide mapping of crustal and uppermost mantle *S*-wave results from seismic refraction data is not yet possible.

The chief advantages of controlled-source seismic-refraction data are: (1) The exact time and position of the seismic sources are accurately known; (2) It is possible to plan, in relation to the specific geologic target, the number, spacing, and geometry of sources and receivers. The main disadvantages of these seismic-refraction data are: (1) The seismic sources are limited to the surface of the Earth, whereas natural seismicity extends to a depth of 10–20 km within the crust, and to a maximum depth of 670 km in subduction zones; (2) There is a practical limit to the strength of chemical or other controlled sources, thereby limiting the depth of investigation to the lithosphere.

It is important to note that vertical-incidence seismic reflection profiles, which are not reviewed here, provide the highest resolution of structural detail within the crust. These data provide an image of the entire crust that is similar to the pictures obtained within sedimentary basins by the oil exploration industry. The application of seismic reflection profiles to the study of the continents began in Germany (cf., discussion in Meissner, 1986), and was adopted in the United States of America in 1974 by COCORP (Barazangi and Brown, 1986a,b). Many other countries soon followed suit

with their own national programs, such as BIRPS (UK, Matthews, 1986), DEKORP (Germany, Meissner *et al.*, 1991). Crustal reflection profiles show that the crust has many fine-scale impedance contrasts that are related to compositional layering, shear zone and fractures, and other geological features, such as dikes and sills (Brown *et al.*, 1983; Matthews, 1986; Meissner, 1986; Barazangi and Brown, 1986a,b; Mooney and Meissner, 1992; Klemperer and Mooney, 1998a,b). Deep reflections from the subcrustal lithosphere have also been recorded in many regions. Consequently, the advent of deep seismic reflection profiling has led to a major new understanding of the evolution of the continental lithosphere. Optimal information is obtained when coincident seismic refraction and vertical-incidence reflection profiles are collected, as has been the case for the Canadian LITHO-PROBE program (Clowes *et al.*, 1999).

Since the early 1950s a large number of seismic profiles have been collected around the world. Advancing technology has led not only to better instrumentation, but also to improved data processing and interpretation techniques. Useful recent reviews of seismic methods for determining crust and upper mantle structure have been provided by Mooney (1989) and Braile *et al.* (1995), whereas Giese *et al.* (1976) summarize older methods of data analysis. Table 1 lists previously published summaries of crustal structure by region covered. The papers and books most comparable to the present work are Soller *et al.* (1982), Prodehl (1984), Meissner (1986), Tanimoto (1995), Pavlenkova (1996), Chuikova *et al.* (1996), and Mooney *et al.* (1998).

Resolution is a major consideration when discussing seismic data. Because of the variety in seismic techniques, however, general statements about resolution are difficult. In seismology, resolution is related both to data quality and physical laws. The quality of a data set is usually considered to be a function of the strength of the signal relative to noise (expressed as signal-to-noise ratio) and the number or density of measurements depending on the number of sources and receivers and their relative spacing. Generally, the more data available, the higher is the resolution. However, physical laws limit the resolution of even near-perfect data sets. The Earth strongly attenuates high frequencies so that signals penetrating deeper will contain relatively low frequencies. Typically, signals traversing the whole crust have peak frequencies of 5–20 Hz resulting in absolute accuracy of depth determination of not better than 2–5% of the depth (e.g., 1–2 km for a 40 km-thick crust).

It is also of interest to use seismic velocities to infer the composition of the lithosphere. This can be accomplished by comparison with laboratory measurements of the seismic velocity of rock specimens believed to have once resided at depth within the lithosphere. This research was pioneered by Francis Birch, who measured numerous igneous rock samples at confining pressures up to 100 MPa and compared these results with early field determinations of seismic velocities (Birch,

1960, 1961). Such measurements have been expanded by others to include metamorphic rocks, the measurement of shear-wave velocities, and the determination of temperature effects (Simmons, 1964; Christensen, 1965, 1966, 1979; Kern, 1978). These studies are reviewed in Holbrook *et al.* (1992), Rudnick and Fountain (1995), and Christensen and Mooney (1995). The interplay of temperature and pressure is worth noting here; a temperature increase of 100°C at constant pressure will decrease seismic velocity by 0.05 km sec^{-1} . However, the influence of increased temperature with depth is compensated for by increased pressure. Thus, seismic velocities will generally increase with depth only if there is a change in rock composition, or an unusually low temperature gradient. An exception is the uppermost (0–5 km) crust, where the closing of cracks in the crystalline crust will lead to an increase in both P - and S -wave velocities.

3. Main Features of Continental Crustal Structure

Over the past 50 y a vast amount of data has been accumulated regarding the seismic structure of the continental crust.

A typical data example is shown in Figure 1. The basic features of continental crustal structure were recognized by the 1960s (Steinhart and Meyer, 1961; James and Steinhart, 1966; Ludwig *et al.*, 1970; Pavlenkova, 1973). The seismic velocity distributions vary widely in different geographic localities, and crustal models generally consist of two, three, or more layers separated by velocity discontinuities or gradients. In relatively stable continental regions the thickness of the crust is between 30 and 50 km. Seismic velocities in the upper crustal layer are usually $5.6\text{--}6.3\text{ km sec}^{-1}$. At a depth of 10–15 km the seismic velocity commonly increases to $6.4\text{--}6.7\text{ km sec}^{-1}$. This velocity increase is sometimes referred to as the Conrad discontinuity, a term that is now in disfavor since the velocity structure of the crust has been found to be sufficiently complex that the use and definition of this term is ambiguous. In many stable continental interiors there is a third, basal crustal layer with a velocity of $6.8\text{--}7.2\text{ km sec}^{-1}$. The seismic velocity below the Moho (P_n velocity) is typically about 8 km sec^{-1} . The exact nature of the velocity–depth distribution is not always well defined. The evidence for distinct layers within the continental crust almost exclusively depends on the interpretation of second-arrival phases. In some regions, clear evidence of later arrivals confirms that the velocity increases discontinuously

FIGURE 1 Sample record section from western China. (a) Shear (S) wave record section with a reduction velocity of 3.46 km sec^{-1} . Shot point corresponds to 0 km ; S_g , direct arrival; S_1S , reflection from boundary between upper and middle crust; S_2S , reflection from middle and lower crust; S_mS , reflection from Moho; S_n , refraction from uppermost mantle. (Wang, Y.X. *et al.*, submitted 2002).

through intermediate layers within the crust, whereas in other regions velocity may increase gradually with increasing depth producing no distinct intracrustal reflection (Levander and Holliger, 1992).

The compilation of seismic crustal data around the world has defined the characteristic primary crustal types connected with specific tectonic settings (Fig. 2). Each primary crustal type is defined by the average seismic model of the crust of a specific age or tectonic setting (Fig. 3).

Despite the abundance of refraction-seismic experiments having been carried out throughout the world, the coverage is very selective (Fig. 4). For example the continents of the northern hemisphere are reasonably well covered, whereas in the southern hemisphere only selective seismic surveys dealing with particular target areas, such as the Andes of South America and the East African Rift System have been studied. Figure 3 shows a world map indicating the main tectonic units of the continents. The map also indicates the location of the seismic cross sections that are discussed later.

Figure 4 shows that Eurasia is densely covered with seismic profiles, as is the central portion of North America (the United States of America and southern Canada). Only limited data are available for northern Canada, Mexico, Central America, and Greenland. The South American and African continents have a concentration of data points in select locations, but vast regions remain without seismic control. Data are lacking for significant portions of the Middle East and Southeast Asia. Data coverage is good within Australia, New Zealand, and the coastal portions of Antarctica. These data points have been used to map the thickness of the Earth's crust (Fig. 5). Crustal thickness is estimated in regions lacking data by determining the geologic setting (Fig. 3) and assuming a typical crustal structural for that setting (Fig. 2). Short period (35–40 sec) Love-wave phase and group velocity maps (Ekström *et al.*, 1997; Ritzwoller *et al.*, 1998), which are mainly sensitive to crustal thickness and average crustal shear velocity, provide a useful guide to estimating crustal thickness in regions lacking active-source seismic profiles (cf., Mooney *et al.*, 1998).

FIGURE 2 Fourteen common continental and oceanic crustal types (Mooney *et al.*, 1998). Typical *P*-wave velocities are indicated for the individual crustal layers and the uppermost mantle. Velocities refer to the top of each layer, and there is commonly a velocity gradient of $0.01\text{--}0.02\text{ km sec}^{-1}\text{ km}^{-1}$ within each layer. The crust thins from an average values of 40 km in continental interiors to 12 km beneath oceans.

FIGURE 3 World map showing six primary Geological provinces and the Figure numbers of cross sections presented in this chapter. Index of locations shown on the map: N-America (Fig. 6) (38° N); N-Chile (Fig. 7); European Geo-Traverse (EGT; Figs. 8 and 9); Russia (Fig. 10); Afro-Arabian rift system (Fig. 11); Australia (Fig. 12); New Zealand (Fig. 13); Japan: northern Honshu (Fig. 14); China (Fig. 15); India (Fig. 16).

FIGURE 4 World map showing the location of seismic refraction profiles used to compile the maps of crustal thickness (Fig. 17) and mean crustal velocity (Fig. 18) (Mooney *et al.*, 1998). Each triangle corresponds to a point along a seismic refraction profile where a crustal column has been extracted.

FIGURE 5 Global crustal thickness (Mooney *et al.*, 1998). The average thickness on continents is 40 km, and generally increases in thickness from 30 km near the margins toward the interior. In this figure, crustal thickness under narrow features (e.g., continental rifts, midocean ridges and oceanic fracture zones) is not visible.

The thickest crust (70+ km) occurs beneath the Tibetan Plateau and the South American Andes. The thickness of continental crust with an elevation above sea level is generally between 28 km and 52 km, and the average thickness (excluding continental margins) is 40 km. Aside from the two regions mentioned above, very little of the continental crust is thicker than 50 km. Likewise, continental crust thinner than 30 km is generally limited to rifts and highly extended crust including continental margins. It is important to bear in mind that the Earth's crust is very complex, and there are numerous local exceptions to these generalizations. In the following sections we provide a detailed description of the structure of the crust on a continent-by-continent basis.

3.1 North America

The deep structure of the North American lithosphere has been the subject of intense investigation since the pioneering work of M.A. Tatel and H.E. Tuve at the Carnegie Institution of Washington in the early 1950s (e.g., Tatel and Tuve, 1955). These and other early investigations established the main feature of a thick (~45 km) crust within the continental interior and thin (~30 km) crust at the margins. They also discovered unexpectedly thin (~30 km) crust beneath the Basin and Range Province, where a high average surface elevation of 1–2 km can be found.

Several summaries of the crustal structure of North America have been published over the past 25 y (Pakiser and Steinhart,

1964; Hart, 1969; Heacock, 1971, 1977; Prodehl, 1977; Pakiser and Mooney, 1989; Mooney and Braile, 1989). A great deal of crustal structure data has also been published by Canadian researchers over the past 15 y under the LITHO-PROBE Program (Clowes *et al.*, 1999). These Canadian investigations have used coincident seismic reflection and refraction data to obtain higher-resolution data than previously was possible. A recent compilation of North American data contains more than 1400 measurements of crustal structure (Chulick and Mooney, 2002).

The contour map of crustal thickness of North America (Fig. 5) shows the previously mentioned pattern of increasing thickness toward the interior. The average thickness of crust is 36.7 km, with a standard deviation (SD) of 8.4 km. The thickest crust (50–55 km) occurs in four relatively isolated regions. The thinnest crust is associated with continental margins and regions that have undergone recent extension, including the Western Cordillera of Canada, the Rio Grande Rift, and the Basin and Range Province.

The upper mantle velocity, P_n , beneath North America is 8.03 km sec^{-1} with a standard deviation of 0.19 km sec^{-1} . Temperature plays a major role in determining P_n velocity, and thus the cold lithosphere of the continental interior typically has a P_n velocity of $8.1\text{--}8.2 \text{ km sec}^{-1}$, whereas velocities of $7.8\text{--}8.0 \text{ km sec}^{-1}$ are measured beneath the warm crust of the Western Cordillera and the Basin and Range Province.

The average P -wave velocity of the crust is related to crustal composition. The global average is 6.45 km sec^{-1}

Many of the features of the lithospheric structure of North America can be seen in a cross section from San Francisco, California, to Washington, DC at 38° N latitude (Fig. 6). This cross section shows that the crust is highly variable in structure. The western USA has a relatively thin crust, averaging 30 km, with a low average crustal velocity (6.2 km sec^{-1}). Surprisingly, a pronounced crustal root does not underlie the topographically high Rocky Mountains. Indeed, the thickest crust (45–50 km) underlies the low-lying Great Plains. The crust thins modestly to the east beneath the Appalachian Foreland, and then thins beneath the Atlantic Coastal Plain. The velocity of the uppermost mantle increases from 7.8–7.9 km sec^{-1} beneath the western USA to more typical continental values of 8.0–8.1 km sec^{-1} beneath the central and eastern USA. A laterally variable *S*-wave low-velocity zone

3.2 South America

Few seismic refraction measurements have been made in South America, with the exception of the Andean region. East of the Andes the crust consists of a collage of Precambrian shields, platforms and paleorifts (Goodwin, 1991, 1996). Sparse refraction data indicate an average crustal thickness of 40 km, with typical shield velocity structure (Fig. 7). This estimate is consistent with phase velocity measurements of surface waves (Ekström *et al.*, 1997) and determinations of crustal structure from passive seismology (Myers *et al.*, 1998).

FIGURE 6 Lithospheric section through the conterminous United States. The section traverses the continent from east to west at approximately 38° N. Solid lines indicate velocity discontinuities where well-determined, dashed lines were inferred. The seismic velocity structure is generalized, and fine-scale structure is not included. The base of the lithosphere is from Iyer and Hitchcock (1989), Pollack and Chapman (1977) and Artemieva and Mooney (2001). Vertical exaggeration is 10:1.

FIGURE 7 East-west lithospheric section through South America at approximately 21° S (see Fig. 4). Vertical exaggeration is 5 : 1. Source: Wigger *et al.* (1994), Giese *et al.* (1999), Patzwahl *et al.* (1999).

The structure of western South America is dominated by mountain building and volcanism associated with the subduction of the Pacific Plate beneath the continent. The structure of the central Andes was first determined from surface wave observations in a classic paper by James (1971) that demonstrated that the high Andes of Peru are underlain by a remarkably thick crust (~60 km). These results have been confirmed by more recent surface-wave phase-velocity measurements (Ekström *et al.*, 1997). In the northern Andes of Colombia, Meyer *et al.* (1976) present a cross section from the Pacific basin into the Western Cordillera. The plate dips at ~15°, and the velocities within the continental crust are higher than average due to the Cenozoic accretion of a basaltic oceanic plateau.

The southern Andes between 19° and 25° S were the subject of numerous seismic investigations during the 1990s by South American, German, and American researchers (e.g., Wigger *et al.*, 1994; Giese *et al.*, 1999; Patzwahl *et al.*, 1999). These studies have contributed a great deal of information regarding the deep structure, and confirm the existence of thick crust south of Peru (Fig. 7). Several detailed seismic offshore and onshore refraction and reflection

profiling campaigns (e.g., Wigger *et al.*, 1994; Patzwahl *et al.*, 1999) were undertaken to investigate the subduction of the oceanic Nazca plate under the South American continent between the Peru–Chile trench and the Central Andes in northern Chile between 19° and 25° S. The active seismic campaigns provided details of crustal and upper mantle structure to depths of 70 km and more, and were supported by long-term passive seismological investigations that resolved structure to more than 100 km. The data clearly show the Nazca plate subducting under an increasing angle of 9–25° down to 30–50 km depth near the coast, and they show a portion of the Moho dipping eastward from 30–50 km near the coast to 55–64 km up to about 240 km inland.

Crustal thickness beneath the western Cordillera and the Altiplano is at least 70 km (Fig. 7). However, only weak Moho arrivals are observed by active seismic measurements beneath the Altiplano and the Western Cordillera. Broadband seismologic data are more reliable in these regions and indicate an approximately 60–70 km thick crust. In the Precordillera a pronounced Moho discontinuity is detected at a depth of 50 km. Along the coast, the oceanic Moho boundary can be identified at a depth of 40–45 km. The seismic measurements

have revealed a clearly pronounced asymmetric structure and evolution of the Central Andean crust.

In the Andean backarc region, tectonic compression has produced pronounced crustal thickening and, locally, a doubling of the Moho discontinuity (Giese *et al.*, 1999). In the forearc region, dehydration of the lower plate may have caused hydration and metasomatism of the overlying mantle wedge that is associated with a decrease in density and seismic velocity to values typical of the crust. Such processes, if real, may reduce the velocity contrast at the Moho and result in a blurring of the crust–mantle boundary from a geophysical point of view. The paleo-Moho today appears as an intra-crustal boundary. Magmatic intrusions and underplating also have the potential to produce new seismic boundaries, including one that appears to be the Moho discontinuity. Giese *et al.* (1999) summarize their interpretation of the Central Andes by suggesting that there exists a variety of different Moho-discontinuities, which they refer to as a “Moho-menagerie”. This term may be understood to refer to a highly complex seismic velocity structure in the lower crust and uppermost mantle.

3.3 Europe and Mediterranean

Europe becomes progressively younger in tectonic age from north to south. The northern Baltic Shield consists of Archean and Proterozoic rocks; to the west of the Baltic Shield the Caledonian orogeny has added crust of Paleozoic age. The basement rocks of central Europe are of Paleozoic age and formed during the Variscan orogeny, covering the area between Scotland and Portugal. The terranes that comprise this region have undergone strong orogenic collapse (extension), as evidenced by a relatively thin lithosphere and crust. The Tornquist Zone separates Paleozoic Western Europe from the extensive Precambrian platform areas of Eurasia. The Neogene Alpine orogeny shaped southern Europe, from the Spanish Pyrenees to the Carpathians, and provide a physiographic separation between central Europe and the Mediterranean.

The European Geotraverse (EGT) was a multinational geologic and geophysical lithospheric investigation carried out in the 1980s that reached from the northernmost tip of Scandinavia to Tunisia in Northern Africa. This investigation include very detailed seismic-refraction surveys, the results of which are summarized in Figure 9.

FIGURE 8 (a) Lithospheric cross section through northern Europe (EGT) (after Ansorge *et al.*, 1992, Figs. 3–18). The section traverses Scandinavia from north to south at approximately 20°E. Depth versus distance is 2:1.

The Baltic Shield has almost no sedimentary cover and is characterized by a generally thick crust with rather high Pg -velocities near the surface. Crustal thickness is 40–50 km and the lower crust shows rather high velocities ($>7 \text{ km sec}^{-1}$). In southern Sweden, several 100 km north of the Tornquist Zone, the crustal thickness decreases to less than 35 km (Fig. 9a), a value that is typical of the Caledonian and Variscan regions of central Europe. Seismic velocities within the crust of the Baltic shield increase gradually from slightly over 6 km sec^{-1} near the surface to $7.0\text{--}7.5 \text{ km sec}^{-1}$ at 40–50 km depth. It is notable that an intermediate crustal boundary, where the velocity increases by $0.1\text{--}0.2 \text{ km sec}^{-1}$, can be followed near 20 km depth throughout the Baltic Shield.

Sub-Moho velocities along the Baltic portion of the EGT are $8.0\text{--}8.2 \text{ km sec}^{-1}$, but velocities as high as 8.5 km sec^{-1} are measured on the adjacent Polar Profile (about 50 km further east). Due to very quiet noise conditions and efficient energy propagation (up to 2000 km), Scandinavia is the only place in Western Europe where seismic penetrations to a depth of 400 km by explosion sources has been achieved (Fig. 8). The model derived from upper mantle arrivals beneath Scandinavia shows several distinct velocity inversions between Moho and 200 km depth (Guggisberg and Berthelsen, 1987). Corresponding S -wave velocities were derived from surface wave studies that were calculated for all of western Europe and thus cover the whole area of the EGT (Ansorge *et al.*, 1992; Mueller and Panza, 1986).

South of the Tornquist Zone, the crust of the Danish and the North German Basins thins significantly to 26 km. Deducting the voluminous sediments, only 15–20 km of crystalline crust remain. A distinct feature underlying the southern end of the North German Basin is the Elbe line. It separates the lower crust into two regions with 6.9 km sec^{-1} average velocity in the north and 6.4 km sec^{-1} in the south (EUGENO-S Working Group, 1998; Prodehl and Aichroth, 1992).

The internal crustal structure throughout the area of the European Variscides (Fig. 9b) is complex and shows considerable lateral variations. Distinct crustal blocks differing in their internal velocity structure can be assigned to geologically defined terranes of the Variscan orogeny. A subdivision of upper and lower crust by a well-defined boundary (Conrad discontinuity) is often, but not always seen. Towards the Alps the average velocity of the lower crust is as low as 6.2 km sec^{-1} , in contrast to the area north of the Swabian Jura where the velocities above the Moho vary between 6.8 and 7.2 km sec^{-1} . The total crustal thickness under the Variscan part of Germany is fairly constant between 28 and 30 km, except under the Rhine Graben area with 25–26 km and beneath the central part of the Rhenish Massif where an anomalous crustal thickening to 37 km is observed. An important point is that the crust consists of only two layers, in comparison with shield crust that is thicker and has three layers, including a high-velocity ($6.9\text{--}7.3 \text{ km sec}^{-1}$) lower crustal layer. A joint consideration of seismic velocity

structure and petrological information from xenolith studies indicates an intermediate-to-mafic composition for the deeper levels of the crust, at least for the central part of the Variscan crust along the European Geotraverse in Central Europe (Prodehl and Aichroth, 1992). More-recent combined reflection/refraction seismic studies have concentrated on the detailed crustal structure of the Saxothuringium terrane of the Variscan orogen in Saxony, southeast Germany (Enderle *et al.*, 1998; Krawczyk *et al.*, 1999) and on seismic signatures of the Variscan Front in southeast Ireland (Masson *et al.*, 1998, 1999).

The southern segment of the European Geotraverse crosses the Swiss Alps, the Po Plain, the Ligurian Sea and the continental fragments of Corsica and Sardinia, and thus covers units with extremely varying lithospheric structure (Fig. 9b) reflecting the collision of Africa and Europe. In combination with seismic-reflection measurements through Switzerland, the EGT data resulted in a complex and detailed model from the Alps to the Apennines, and demonstrates their asymmetric crustal structure (Valasek *et al.*, 1991, Blundell *et al.*, 1992, Pfiffner *et al.*, 1997). The major element in the upper crust of the central Alps is the relatively low velocity beneath the Aar Massif compared with the well-documented higher velocities in the metamorphic crystalline nappes of the Penninic zone (Pfiffner *et al.*, 1997). From the northern margin of the Alps, the crust steadily thickens southwards to about 60 km underneath the central Alps. The image obtained from combined reflection and refraction data indicates that the European lower crust is a pre-Alpine, possibly Variscan, feature and extends relatively undisturbed from the northern Molasse basin to about 120 km south of the northern margin of the Alps where it is subducted beneath the Adriatic microplate. A fault-like step of the Moho is indicated underneath the Insubric line, which is the tectonic boundary between the central and southern Alps, and as such is possibly the surface expression of the boundary between the European and African crust. Seismic reflection and refraction data indicate that the Adriatic lower crust has been driven northward as a wedge between the European upper and lower crust (Ansorge *et al.*, 1992; Mueller and Kahle, 1993; Valasek *et al.*, 1991; Waldhauser *et al.*, 1998). The complicated arrangement of the various plates in the Southern Alps can best be viewed in enlarged Moho contour maps and 3D block diagrams for this area (Ansorge *et al.*, 1992; Waldhauser *et al.*, 1998).

Egger (1992) provides a detailed discussion of the seismic refraction data of the southern segment of the EGT from northern Apennines into Tunisia. The results support the hypothesis that the opening of the Provencal basin, the rotation of Corsica and Sardinia, and the opening of the Tyrrhenian Sea belong to a system of back-arc spreading, with subduction as a counterpart that is active beneath the Calabrian arc in southern Italy. Complete crustal surveys across the margins and deep basins have complimented the EGT seismic survey to elucidate the nature of the crust at the incipient and ongoing

FIGURE 9 Crustal cross section through Europe along the European Geotraverse (EGT) (after Ansorge *et al.*, 1992, Figs. 3–4, 6, 9, 11, 12, 15, 16). Depth versus horizontal distance is 10:1. (a) Section through Scandinavia at approximately 20° E, (b) Section through central and southern Europe traversing central Germany, the Alps, the Apennines of northern Italy, Corsica, Sardinia and Tunisia at approximately 10° E.

ripping in the Ligurian Sea and the structure of the Sardinia Channel north of Tunisia. Corsica and Sardinia show a typical, 30-km thick Variscan crust (two layers with average velocities of 6.2 and 6.8 km sec⁻¹), underlain by *Pn*-velocities increasing gradually from 7.6 km sec⁻¹ under northern Corsica to 8.0 km sec⁻¹ under southern Sardinia and the Sardinia Channel (Fig. 9b). The crust thins to 20 km under the Ligurian Sea and Sardinia Channel.

The EGT reaches African continental crust in Tunisia. The crustal thickness increases steadily from 21 km under the center of the Sardinian Channel to 38 km in the central folded Atlas, from where it decreases southward to 33 km under the southern end of the traverse (Fig. 9b). The velocity of the uppermost mantle is 8.0–8.1 km sec⁻¹. There are thick post-Paleozoic sediments varying in thickness from 8 km in the north to 3 km in the south. A velocity of 6 km sec⁻¹ is found everywhere at unusually great depths of 8–14 km. Other striking features are the low average velocity of the entire crust of 6.05 km sec⁻¹ and the lack of any clear intracrustal layering (Ansorge *et al.*, 1992; Buness *et al.*, 1992).

Several large-scale seismic investigations have provided further details on the crustal structure of Europe. To the east of the EGT profile, Abramovitz *et al.*, (1999) describe the crustal structure of the North Sea (that portion due north of the Netherlands) and western Ireland. Both regions have thin (30–32 km) crust with three layers. To the east of the EGT profile, the POLONAISE and EUROBRIDGE projects investigated the crust of Precambrian and Variscan Europe, as described by Guterch *et al.* (1999), Grad *et al.* (1999), and the EUROBRIDGE Seismic Working Group (1999). These data document that the crust thickness from 32 km beneath the Paleozoic Variscan Europe to 42 km beneath the Precambrian East European Platform. The Precambrian crust has a very well-defined three-layer structure with seismic velocities in the upper, middle, and lower crust of 6.2, 6.6, and 7.1 km sec⁻¹ respectively (Sroda *et al.*, 1999). This is in contrast to the two-layer crust of central Europe, as described above (Fig. 8).

3.4 Northern Eurasia

Seismic refraction profiles cover all of the major geologic structures of northern Eurasia, including Precambrian and younger platforms and shields, deep depressions (e.g., Caspian Sea), orogenic belts (e.g., Urals and Tien Shan Mountains), rifts, and marginal and inner seas. The crustal structure for three long-range profiles is summarized in Figure 10: (a) Black Sea to Dnieper-Donetz basin, (b) Baltic Shield to West Siberian Plate (passing through the Urals); and (c) West Siberian Plate to Siberian Craton. The first profile was carried out in the 1960s on a closely spaced profile with a 100 m distance between seismometers and chemical explosions at 50–60 km intervals (“continuous profiles”; Pavlenkova, 1973). The long-range profiles from the Baltic Shield across the Urals to the West Siberian Plate and from the West Siberian Plate to the Siberian

Craton were recorded with a 10 km interval between seismometers and two types of explosions: chemical and Peaceful Nuclear Explosions (PNEs). The latter profiles provided arrivals from the upper mantle to a depth of 700 km (Egorkin *et al.*, 1987; Belousov *et al.*, 1991; Mechie *et al.*, 1993). For all of these profiles, the crustal structure can be described by four layers with the following seismic velocities: 2.0–5.5 km sec⁻¹ (sediments), 5.8–6.4 km sec⁻¹ (upper crust), 6.5–6.7 km sec⁻¹ (middle crust) and 6.8–7.4 km sec⁻¹ (lower crust).

The first profile (Fig. 10a) crosses the Black Sea basin, Crimean Mountains, Sivash Basin, Ukrainian Shield, and the Dnieper-Donetz Basin (Fig. 3). The Ukrainian Shield has a crustal thickness of more than 40 km and consists of three crustal layers, each with a thickness of 10–15 km. Beneath the basins the Moho is uplifted and the upper crustal layer thins. Such changes in crustal structure become even more dramatic in the Black Sea area where the consolidated crust is only 20 km thick and where the upper and lower crustal layers are absent. The adjacent Crimean Mountains have a deep crustal root, and the crustal average velocity is slightly lower than in the Ukrainian Shield.

The second profile (Fig. 10b) crosses the Baltic Shield, Russian Platform, Timan–Pechora plate, Ural Mountains, and West Siberian Platform. These tectonic units have similar crustal structure, an exception being the Timan–Pechora plate. This plate is characterized by considerably lower average crustal velocity, because a lower-crustal high-velocity layer ($V_p > 7$ km sec⁻¹) is absent. The Urals have a pronounced crustal root, whereas the Timan ridge is compensated by an increased thickness of the upper crust. Below the crust, strong reflections are recorded from a velocity discontinuity (referred to in Russian literature as the “N discontinuity”) at depths of 70–90 km. The relief on this boundary appears to be opposite to that of the Moho. The seismic velocity between the Moho and the N discontinuity varies from 8.0 beneath the Pechora and West Siberian plates to 8.4 beneath the Urals. These changes clearly correlate with measured heat flow, with the lower velocities corresponding to higher heat flow areas. An anomalous high-velocity zone was revealed near the boundary between the old Russian plate and the younger Timan–Pechora plate. The dotted line in Figure 10b traces this zone from a high-velocity intrusion in the crust to the north where it is subducted beneath the Pechora Plate.

The third profile (Fig. 10c) crosses the West Siberian plate and the Siberian Platform. Though of differing age, these platforms have similar crustal thickness. Lateral variations in crustal structure are mainly noted beneath deep sedimentary basins. For example, beneath the West Siberian basin and the Tunguss basin the thickness of the middle crustal layer is nearly constant, whereas the thickness of the lower crust increases. The Vilui basin, which is younger than the Tunguss basin, has a clear Moho uplift. The upper mantle velocities hardly change along this profile. The only characteristic feature is the region with lower velocity (8.0 km sec⁻¹) in the

FIGURE 10 Crustal cross sections through Eurasia (Egorkin *et al.*, 1987; Beloussev *et al.*, 1991). (a) Black Sea–Dnieper-Donetz basin. The section traverses southeastern Russia in a SSW–NNE direction from about 45° to 53° N and 34° to 40° E. Depth versus horizontal distance is 5 : 1. (b) Baltic Shield – Urals – West-Siberian Plate. The section traverses northwestern Russia in a WNW–ESE direction from about 69° to 62° N and 30° to 72° E. A seismic discontinuity ("N") within the uppermost mantle is often reported beneath northern Eurasia (e.g., Pavlenkova, 1996) but has not been well determined elsewhere. Depth versus horizontal distance is 6 : 1. (c) West-Siberian Plate–Siberian Platform–Vilui Basin. The section traverses northeastern Russia in a W–E direction from about 65° to 62° N and 66° to 132° E. Depth versus horizontal distance is 10 : 1.

central West Siberian plate. This location corresponds to a prominent rift zone that crosses the plate from north to south. Below the crust, an important feature is an upper mantle low-velocity zone (8.0 km sec^{-1}) immediately above the N boundary, which is at a depth of 100 km.

3.5 Near East and Africa

The Near East and Africa are largely underlain by Precambrian cratons, with, in comparison to other continents, a very small fraction of the crust being of younger age. The younger crust occupies the Cape, Mauritanide, and Atlas fold belts, located at the south, northwest, and north margins, respectively. The geologic evolution of the African continent began in the Early Archean Eon, 3.2–3.65 Ga with the formation of the Kaapvaal craton of southern Africa. The entire landmass was assembled and stabilized by 0.6 Ga. The main tectonic events since the end of the Precambrian have been: (1) the Mesozoic and Cenozoic rifting at the west margin during the opening of the south Atlantic Ocean; and (2) rifting in East Africa and the Red Sea in the late Cenozoic.

As is evident in Figure 4, large portions of Africa have not been investigated by seismic refraction profiles. Major crustal seismic research has been carried out in the Afro-Arabian rift system and its immediate surroundings of eastern Africa (Prodehl *et al.*, 1997). The crustal and uppermost-mantle structure has been investigated by seismic refraction surveys in the Jordan–Dead Sea rift, the Red Sea, the Afar depression and the East African rift of Kenya (Fig. 11). With the exception of the Jordan–Dead Sea transform, the entire Afro-Arabian rift system is underlain by anomalous mantle with Pn -velocities less than 8 km sec^{-1} , while under the rift flanks the Pn -velocity is clearly equal to or above 8.0 km sec^{-1} . Various styles of rifting have been found. Oceanic crust floors the axial trough of the southern Red Sea rift, thinned continental crust underlies the margins of the Red Sea, Afar depression, and northern Kenya rift. In contrast, 30–35 km thick continental crust is found both under the Jordan–Dead Sea rift, an area of strike-slip rifting, and under the central Kenya rift, where updoming driven by a buoyant mantle is apparently the controlling feature. The transition from thinned continental crust to 5–6 km thick oceanic crust in the center of the Red Sea appears to be gradual. In contrast, the transition from the thin crust of the East Africa rift to undisturbed continental crust of $40 \pm 5 \text{ km}$ thickness is mostly rather abrupt. The seismic data indicate various stages of rifting, and imply the presence of hot uppermost mantle under most parts of the rift system, possibly related to plume activity. Volcanism may disrupt and/or underplate the crust in places, altering particularly the lower crust.

Portions of northern Africa have been investigated with seismic profiles. Measurements in Tunisia were completed as part of the European Geotraverse of 1982–1985, and are summarized in Section 2.3 and Figure 9. In addition,

a geological and geophysical transect was completed through the High Atlas Mountains in Morocco. These mountains were formed over a major intracontinental rift system that had extended from what is now the Atlantic margin of Morocco to the Mediterranean coast of Tunisia ($\sim 2000 \text{ km}$) during the convergence of the African and European plates.

Crustal thickness variations in the region highlight one of the more remarkable aspects of this orogen. Despite topography that is locally in excess of 4 km, there does not seem to be crust that is thicker than 40 km. Beauchamp *et al.* (1999) report thin crust (18–20 km) beneath the Moroccan shelf and a thickness of 30 km south of the High Atlas Mountains. The crust thins to 24 km toward the Atlantic margin, and attains an average crustal thickness of 35 km to the north of the mountains. The crust is 39 km thick beneath the mountains. There is also evidence for a low-velocity zone at depths of 10–15 km beneath the High and Middle Atlas Mountains. This may be due to a crustal detachment located at the base of the Paleozoic (Beauchamp *et al.*, 1999).

3.6 Australia, New Zealand, and Antarctica

Australia is a stable continent that is largely isolated from the immediate effects of plate tectonics. Within its interior it contains no active rift systems, and only at its offshore northern domain does an active convergent margin exist. The central and western portions of the Australian continent are very ancient. Its western Archean cratons (Pilbara and Yilgarn) have yielded some of the oldest geochronologic ages ($>4.0 \text{ Ga}$) determined so far, and the midcontinent is composed of Proterozoic crust. The eastern third of the continent and the Tasmanides, are Paleozoic and Mesozoic in age (Drummond, 1991).

Since the early 1950s, a considerable body of data has accumulated on the crustal structure of the Australian continent. Cleary (1973), Finlayson and Mathur (1984), Drummond and Collins (1986) and Collins (1988, 1991) summarize this work. These active-source results cluster at specific areas (Fig. 12). However, a recent study based on receiver functions has made possible the determination of a comprehensive Moho map (Clitheroe *et al.*, 1999).

The crust is thickest beneath the Proterozoic North Australian Craton (45–50 km), Central Australia ($>50 \text{ km}$), and under the Paleozoic Lachlan Fold Belt (40–50 km). It is shallowest under the Archean Pilbara and Yilgarn Cratons of Western Australia (28–37 km), and possibly Tasmania (25–35 km). Pn -velocities are generally greater than 8 km sec^{-1} . They are around 8.2 km sec^{-1} and higher in central Australia, slightly lower under the thinner western Australian Pilbara and Yilgarn cratons, and seem to be lowest under eastern Australia along the Great Eastern Divide and the Tasman Geosyncline.

New Zealand lies across the Australian/Pacific plate boundary that transects the South Island. Davey *et al.* (1998)

FIGURE 11 (a) Location of long-range seismic lines in the Afro-Arabian rift system (Prodehl *et al.*, 1997). Continuous lines: seismic-refraction surveys, full circles mark shotpoints where locations were published. Dashed lines: approximate lines through epicenters of local earthquakes, crosses: IRSAC (Institut pour la Recherche Scientifique en Afrique Centrale) network at Zaire. (b) Velocity–depth columns through the Afro-Arabian rift system. The evolutionary sequence [for locations see Fig. (a)] illustrating the variation in crustal thickness under the Afro-Arabian rift system from the Jordan–Dead Sea transform system through the Red Sea, Gulf of Aden and Afar triangle to the southern end of the Kenya rift. M, Moho. Depths refer to sea level. Numbers of crustal columns refer to (a) (Prodehl *et al.*, 1997).

and Stern and McBride (1998) present the crustal structure of the South Island based on recently recorded seismic refraction and near-vertical reflection data (Fig. 13). These results indicate that the crust has been formed by the accumulation of low-grade metasedimentary rocks in a convergent margin setting. Modeling of both onshore and offshore data indicate a crust of fairly constant P -wave velocity (5.9 – 6.2 km sec $^{-1}$) overlying a 5 – 10 km-thick lower crust with seismic velocity of about 7 km sec $^{-1}$. The crustal structure

(Fig. 13) is remarkable for the unusual thickness of low-velocity materials that extend along the Alpine fault zone. The total crustal thickness varies from about 30 km at the east coast to about 42 km under the western mountains, the Southern Alps.

Antarctica is divided by the Trans-antarctic Mountains into East Antarctica, a Precambrian craton, and West Antarctica, which has experienced significant Cenozoic tectonic activity, including crustal extension. Relatively few measurements of

FIGURE 12 Crustal structure of Australia (Collins, 1991): (a) Location of major geological provinces and selected seismic profiles (solid lines); (b) Moho depths in Australia; patterns show regions with similar values, numbers indicate point values. Western Australia is composed of Precambrian crust, including some of the most ancient cratons on Earth (Archean Pilbara and Yilgarn blocks). These Archean cratons have a crustal thickness of 28–37 km, which is less than the global continental average of 40 km.

FIGURE 13 Seismic section across the South Island of New Zealand (Stern and McBride, 1998) showing western-thickening crust and east-dipping Alpine fault zone. The crustal structure is unusual in showing low seismic velocities ($5.2\text{--}6.2\text{ km sec}^{-1}$) throughout the crust. This indicates that the entire crust, above the hypothesized oceanic crustal layer ($6.7\text{--}7.1\text{ km sec}^{-1}$), is composed of low-grade metasedimentary rocks.

crustal structure have been reported for the continental crust of Antarctica. The top of basement in western Antarctica lies at least 2 km below sea level and drops an additional 2 km beneath the deeper parts of the Byrd Subglacial Basin. In the east, the basement is found very close to sea level, and the

overlying section is typically no more than a few hundred meters thick. Seismic velocities in the upper crust range from 5.7 to 6.4 km sec^{-1} (Bentley, 1991).

The best information on deeper crustal structure comes from seismic refraction profiles. In the east, two profiles in Maud Land show a depth to Moho of 38–40 km inland, which decreases to about 30 km near the coast. On one of the profiles, a pronounced intracrustal (Conrad?) discontinuity was found at a depth of 18 km between layers with seismic velocities $6.0\text{--}6.2\text{ km sec}^{-1}$ above and $6.7\text{--}6.9\text{ km sec}^{-1}$ below. The apparent P -wave velocity in the upper crust ranges from 6.0 to 6.4 km sec^{-1} and appears to gradually increase with depth (Bentley, 1991).

In the Amery ice shelf, Bentley (1991) describes a layered continental crust with thickness ranging from 30 to 40 km. The upper crustal layer is about 20 km thick. The seismic velocity seen in this section of upper crust is somewhat higher than expected, and may be due to the great age of the crystalline rocks in the basement.

In western Antarctica, a deep sounding in front of the Weddel Sea found the Moho at 33–36 km depth, but it shallows to about 30 km beneath the Crary Trough, then quickly drops to 40 km beneath Coats Land. The lower crustal layer is about 10 km thick. In the east, however, 15 km from the shoreline, the crust–mantle boundary is found to lie 25 km below sea level. From this point, the Moho depth increases to 28 km toward the west (beneath Ross island), and to 35 km eastward

(at the shoreline). There is only one additional unpublished seismic profile available for western Antarctica, and this profile shows Moho depth at 24 km below sea level.

In summary, the mean thickness of the crust in East Antarctica is approximately 40 km compared to 30 km in West Antarctica, and the boundary between the two is abrupt. There is a precipitous drop in topography at the Trans-Antarctic Mountains, and geophysical evidence also implies that this change in crustal thickness is sudden.

3.7 Japan and Southeast Asia

The opening of the Sea of Japan in the early Miocene rifted Japan from the Asiatic margin (Finn *et al.*, 1994). Present-day Japan has a composite structure composed of Mesozoic metamorphic and plutonic rocks, and Cenozoic volcanic and plutonic rocks associated with active subduction and magmatism. The seismic structure of Japan has been investigated for many years (e.g., Matsuzawa, 1959; Asano *et al.*, 1979), and abundant seismicity within the crust and upper mantle has permitted detailed modeling of lithospheric structure (Zhao *et al.*, 1990). Iwasaki *et al.* (1994) provide a detailed interpretation of the *P*- and *S*-wave structure of the crust of northern Honshu (Fig. 14). The crust is about 33 km thick, and shows a nearly uniform increase in velocity with depth from

6.0 km sec^{-1} (beneath a 1-km thick layer of sediments and/or volcanic rocks) to 7.0 km sec^{-1} at the base of the crust. The seismic velocity of the uppermost mantle is unusually low, $7.5\text{--}7.6 \text{ km sec}^{-1}$, a value that is found only in regions of very high heat flow and/or active volcanism, such as the Afro-Arabian rift system (Fig. 11).

Indonesia has had a complex geologic history, and the physical properties of the crust are largely undetermined. Most likely the area consists of a continental or borderland type of crust of intermediate (30 km) thickness. It has been proposed that cratonization of mobile shelves occurs by sedimentary and calcalkaline accretion, following in the wake of island arc migration by backarc extension (Curry *et al.*, 1977).

The Gulf of Papua has been the focus of study by a number of researchers. Drummond *et al.* (1979) found sediments to be 5 km thick on the Papuan Plateau, but 10 km to the west and northwest along the axes of the Moresby and Aure Troughs. Offshore, sedimentary basins as thick as 11 km have been measured. Beneath these sediments, a layer with *P*-wave velocity of 6.1 km sec^{-1} was inferred over the region, but was thought to be underlain to the south by a layer with a velocity of 6.9 km sec^{-1} . This second, faster, layer is also thought to be present beneath the Eastern Plateau. This lower-crustal layer is noticeably absent from the Aure Trough in the north, though velocity increases are expected with depth.

FIGURE 14 Crustal *P*-wave and *S*-wave velocity structure through a typical island arc: the Kitakami region, northern Honshu, Japan. Indicated are *P*-velocity/*S*-velocity, and their ratio. Modified from Iwasaki *et al.* (1994).

The Moho is 27–29 km deep along the southwestern coast of the peninsula and shallows beneath the Moresby Trough to 19 km. This depth is greater than normal for the Moho beneath oceanic crust, but it is not unreasonable when compared to other measurements in the area. Curry *et al.* (1977) found

the Moho to be at 18 km depth south of the Island of Bali and 21–25 km south of the Island of Java.

Beneath the Eastern Plateau, the Moho again deepens to 25 km (Drummond *et al.*, 1979). With a lower crustal layer of 9 km in thickness, the crust beneath the Papuan Peninsula is

FIGURE 15 Crustal structure of China (Li and Mooney, 1998): (a) Tectonic sketch map of China with location of seismic crustal surveys; (b) Representative seismic velocity–depth functions for nine regions of China. The crust thickens from about 35 km in the east to greater than 70 km beneath the Tibetan Plateau to the west.

therefore continental. Offshore, the crust in the Moresby Trough is about 19 km thick, with sediments comprising about the top 10 km. Therefore, the crust below the sediments has a thickness typical of oceanic crust. The northern extent of the thin crust beneath the Moresby Trough is uncertain. Similar measurements of crustal thickness to those of Drummond *et al.* (1979) were made in Papua by Finlayson *et al.* (1976), who detected a low-velocity zone below the Moho and a return to normal upper-mantle velocities at a depth of about 50 km.

3.8 China and India

China has undergone a long geologic evolution, from the formation of the Archean Sino-Korean platform in the north to the active continent-continent collision in Tibet. More than 36 000 km of active-source seismic refraction profiles (referred

to as Deep Seismic Sounding, DSS, profiles, in the Russian, Chinese, and Indian literature) have been collected in China since 1958. The most remarkable aspect of China's crustal structure is the >70 km thick crust of the Tibetan Plateau (Fig. 15). All of western China is underlain by crust that is 45–70 km thick and is separated from 30–45 km thick crust of Eastern China by a seismic belt which trends roughly north-south at 105° E longitude. The crustal structure of western China (Fig. 15b, columns a–d) show thick crust that is characteristic of young orogenic belts worldwide. Three of the four columns differ from the thick crust of shields in that they lack a high-velocity (7.0–7.5 km sec⁻¹) lower crustal layer (cf. Christensen and Mooney, 1995). A high velocity (7.1 km sec⁻¹) lower crustal layer has been reported in western China beneath the southernmost portion of the Tibetan Plateau. Several investigators have identified this layer as the cold lower crust of the subducting Indian plate (cf. Li and Mooney, 1998).

FIGURE 16 Lithospheric cross-section of the Indian subcontinent compiled from sources listed in the text. Inset shows the location of the cross section. The crustal structure is highly variable laterally, but the crustal thickness, where measured, is relatively uniform at about 40 km, equal to the global average for Precambrian cratonic crust. Estimated lithospheric thickness ranges from 80 to 150 km, and is greatest beneath the Bundelkhand (BUC) and the Bhandara (BHC) cratons.

Recently recorded near-vertical and wide-angle reflection data indicate a low-velocity, perhaps fluid-rich or partially molten zone in the middle crust of the Tibetan Plateau (Zhao *et al.*, 1993; Nelson *et al.*, 1996; Makovsky *et al.*, 1996a,b).

The crustal columns for eastern China (Fig. 15b, columns e–i) all indicate relatively thin (29–33 km) crust, close to the continental global average for extended crust (30 km), but significantly thinner than the global average of 39 km (Christensen and Mooney, 1995).

The average crustal velocity of China (6.15–6.45 km sec⁻¹, Fig. 15b) indicates a felsic to intermediate bulk crustal composition. Upper mantle *Pn* velocities (about 8.0 km sec⁻¹) are equal to the continental global average. These results have been interpreted in terms of the most recent thermo-tectonic events that have modified the crust (Li and Mooney, 1998). In eastern China, Cenozoic extension has created a thin crust with low average crustal velocities while in western China, Mesozoic and Cenozoic arc–continent and continent–continent collisions have led to crustal growth and thickening.

India consists of Archean cratons and associated Archean to Proterozoic high-grade mobile belts, Proterozoic sedimentary basins, horst and graben belts associated with Gondwana sedimentation, Deccan volcanism, and the Himalayas. The investigation of the crustal structure of India by seismic refraction profiling was begun in 1972 as an Indo-Soviet cooperation. Since then, more than 20 long-range refraction, near-vertical reflection and wide-angle reflection profiles have been carried out. Results are reviewed by Kaila (1982), Kaila and Krishna (1992), Mahadevan (1994), Reddy (1999) and Reddy and Rao (2000). Estimates of crustal thickness are in the 35–40 km range, with the exception of the Himalayas that are known to have thicknesses of about 70 km (Mahadevan, 1994). A lithospheric cross section compiled from several seismic profiles illustrates the main properties of the seismic structure of the crust and uppermost mantle of India (Fig. 16).

4. Summary Discussion

4.1 Histograms of Crustal Thickness and Average Crust Velocity

We have divided the crust into six geologic provinces (Fig. 3) and present histograms for two basic properties: crustal thickness (Fig. 17) and mean crustal velocity (Fig. 18; Mooney *et al.*, 1998). These histograms reinforce many of the points made earlier regarding the relationship between the seismic structure of the crust and geologic setting. Shields and platforms have an average crustal thickness of about 40 km, with a standard deviation (SD) of 7 km. Shields have the highest average *P* velocity of any geologic province, 6.49 km sec⁻¹ (SD 0.23 km sec⁻¹). Orogenic crust has a wide range of

thickness of 20–80 km, and an average thickness of 43 km (SD 10 km). Isostatic forces uplift crust thicker than about 50 km, leading to erosion and crustal thinning. Most thick (>50 km) crust is young orogenic crust that is undergoing active tectonic compression. The average *P* velocity of orogenic crust is 0.13 km sec⁻¹ lower than shield crust. This may be due to thickening of low-velocity upper crustal layers during compression, as seen in the European Alps, intrusion by silicic magma, such as are seen in the Andes, or by the delamination of the high-velocity lower crust, as found beneath the southern Sierra Nevada, California.

Extended crust refers to crust that has experienced localized rifting and/or regional extension. Examples include the Basin and Range province of the western USA (Fig. 6) and much of Western Europe. The average thickness of extended crust is about 30 km, and the mean *P*-wave velocity (6.16 km sec⁻¹) is 0.33 km sec⁻¹ lower than shield crust. Forearc crust refers to those regions that were formed in front (oceanward) of a volcanic arc, such as many parts of the west coast of North America. Only 26 seismic refraction measurements are presently available for forearcs. These regions have an average crustal thickness of 27 km (SD 8 km) and a very low mean crustal velocity (6.09 km sec⁻¹). These values reflect the abundant sedimentary accumulations in forearc crust. Magmatic (volcanic) arcs, such as Japan (Fig. 14) and the Aleutian Islands, Alaska, have an average crustal thickness of 31 km (SD 8 km) and a mean *P*-wave velocity of 6.14 km sec⁻¹ (SD 0.23 km sec⁻¹).

4.2 General Characteristics of Continental Crustal Structure

The continental lithosphere shows several important regularities. (1) Crustal thickness and average velocities increase from continental margins toward the interior; (2) The crust of old, stable shields and platforms is 35–45 km thick, whereas young, nonorogenic crust is significantly thinner (25–35 km); (3) An inverse correlation is clearly evident between the depths to the basement and to the *M* boundary: the crust is thicker under orogenic belts, and thinner under basins; (4) An average petrological model may be presented for stable continental interiors in terms of three layers. The two upper layers have silicic-to-intermediate composition, but the middle crust is composed of rocks with a higher degree of metamorphism. The third layer is composed of mafic rocks of granulite-grade metamorphism. The composition of the continental crust is discussed in detail by Rudnick and Fountain (1995) and Christensen and Mooney (1995); (5) The upper mantle, including the subcrustal lithosphere and possibly the asthenosphere, is characterized with fine-scale seismic and rheological stratification. Rheologically weak layers appear in the middle and lower crust, and the crust/mantle boundary. In northern Eurasia, a thin low-velocity zone is reported at a depth of 80–100 km based by a clear “N” reflector

FIGURE 17 Histograms of crustal thickness for six continental tectonic provinces calculated from the individual point measurements (triangles) of Figure 4 (Mooney *et al.*, 1998). Average and SD are indicated. These histograms indicate systematic differences among tectonic provinces, and provide a basis for extrapolating crustal thickness into unmeasured regions.

(Pavlenkova, 1973, 1996; Zverev and Kosminskaja, 1980; Belousov and Pavlenkova, 1984; Kozlovsky, 1987; Belousov *et al.*, 1991; Krilov *et al.*, 1991, Puzyrev, 1993); (6) The thickness of the crust usually increases under orogenic belts. The depth of crustal roots varies in different kinds of orogens. The thickest crust is under young mountains, such as those situated on Alpine geosynclines (Caucasus, Pamir). In contrast, orogens developed on ancient platforms have smaller roots (e.g., the northern Tian-Shan and the Altai Mountains). There are also orogens that lack roots, such as the Canadian Cordillera (Clowes *et al.*, 1999), and that are held up by low density, buoyant mantle.

In most cases there is an inverse correlation between sediment thickness and depth to the Moho. For example, crustal thickness decreases under platform depressions, the basins of the inner and marginal seas, and under rifts. There is an inverse correlation between crustal thickness and heat flow. This correlation is observed both in active regions and on stable platforms.

As noted above, stable continental crust is 40 ± 7 km thick with three main crustal layers, each 10–15 km thick. This crustal type covers the interior of Eurasia, North America, Africa, and Australia. Thin (25–35 km) two-layer continental crust is observed on the marginal parts of Eurasia, in Western Europe, in the Pechora Plate of north central Russia, in the Far

FIGURE 18 Histograms of mean crustal velocity for six continental tectonic provinces calculated from the individual point measurements (triangles) of Figure 4 (Mooney *et al.*, 1998). Average and SD are indicated. These histograms indicate systematic differences among tectonic provinces, and provide a basis for extrapolating mean crustal velocity into unmeasured regions.

East, Eastern China, and the Basin and Range Province, western United States of America. It differs from the stable crust not only in thickness but also by virtue of a lower mean crustal velocity (6.16 km sec^{-1} versus 6.49 km sec^{-1}). An important characteristic feature of this crustal type is the absence of the high-velocity layer (7 km sec^{-1}) in the lower crust.

A consideration of more than 1000 seismic refraction profiles worldwide lends strong support to the definition of the seismic Moho as that depth where seismic velocity first exceeds 7.6 km sec^{-1} . The Moho is nearly always evident as a refraction horizon, and can be clearly distinguished from

the lower crust. The uppermost mantle, including the lithosphere and asthenosphere, is sometimes characterized by fine stratification; high velocities (up to $8.4+ \text{ km sec}^{-1}$) alternate with lower ones ($7.8\text{--}8.0 \text{ km sec}^{-1}$). There is a close correlation between the properties of the crust and upper mantle; stable shield and platform crust exists above cold, high-velocity uppermost mantle, and thin, extended or young orogenic crust exists above low velocity regions. This correlation indicates that mantle processes play an important role in crustal evolution, such as providing a driving force for crustal extension.

This brief review of the seismic velocity structure of the continental lithosphere highlights only the general features of its structure. The focus has been on the structure of the upper portion of the lithosphere, the continental crust. A great deal of new, high-quality data are recorded each year, and these show that the lithosphere to be highly complex and subject to multiple processes, including compression accompanied by brittle faulting and ductile deformation, extension, displacement by strike-slip faulting, and modification by igneous processes. Controlled source seismic data have been important in developing an understanding of the structure, composition, and evolution of the lithosphere, but future progress will depend on investigations that combine geophysical, geologic, and geochemical constraints.

Acknowledgments

It is a pleasure to acknowledge our colleagues at the US Geological Survey, numerous US academic institutions, the Lawrence Livermore and Los Alamos National Laboratories, the Universities in Karlsruhe (Germany), Paris, and Strasbourg, the Institute of the Physics of the Earth, and the Russian Ministry of Natural Resources, and Russian Academy of Sciences. Review comments by R. Meissner, H. Kanamori, P.R. Reddy, I. Artemieva and an anonymous reviewer are appreciated. Special thanks to W.H.K. Lee for his encouragement, and to K. Favret (USGS) for making the figures. S. Detweiler (USGS) assisted with preparation of the final manuscript.

Seismic Structure of the Oceanic Crust and Passive Continental Margins

T.A. Minshull

Southampton Oceanography Centre, Southampton, UK

1. Introduction

The oceanic lithosphere covers approximately 60% of the Earth's surface. Well-constrained measurements of the seismic velocity structure of the crust and upper mantle beneath the ocean floor are sparse. However, the crustal structure appears to vary systematically with a rather small number of parameters: the age of the lithosphere; the spreading rate at which the crust was formed; its position with respect to offsets in the ridge axis; and the proximity or otherwise of thermal or chemical perturbations such as mantle plumes at the time of crustal formation or later in its history. Significant portions of this parameter space remain to be explored. However, the available data do allow various empirical correlations to be made, and numerical modelling of the processes governing the formation and evolution of the oceanic crust allow some of these correlations to be tied to the physics of these processes, so they can be used as predictive tools in poorly explored areas. The printed version of this chapter is abstracted from a longer, fully referenced version on the attached Handbook CD, to which the reader is referred for further details.

2. Methodology

Single and multichannel seismic reflection profiling (Fig. 1a) has provided considerable detail on the thickness and internal structure of the <1–2 km sediment layer which typically covers oceanic basement, and limited information on structures within the basement. Some information on seismic velocities can be gleaned from multichannel reflection data, from vertical seismic profiles and from local earthquake seismology. However, the vast majority of our knowledge of the seismic velocity structure of the oceanic crust and uppermost mantle comes

from seismic refraction (or “wide-angle seismic”) experiments. The earliest experiments in the 1950s and 1960s used two ships, one of which fired explosive shots at intervals of several kilometers while the other held station with a hydrophone

FIGURE 1 Methodology for seismic experiments on oceanic crust. (a) Multichannel seismic reflection. (b) Seismic refraction using ocean bottom seismometers or hydrophones. Ray paths for the main crustal signals P_2 (turning in Layer 2), P_3 (turning in Layer 3) and PmP (reflecting at the Moho) are shown.

receiver. The hydrophone signal was recorded directly onto paper rolls, first-arrival travel times were picked and velocities were inferred using simple graphical methods (e.g., Raitt, 1963). This early exploration phase provides the only available data from many areas of the oceans.

The use of internally recording free-floating sonobuoys later allowed seismic refraction experiments to be conducted from a single ship. By the early 1980s these were replaced by ocean bottom hydrophones (OBH) and seismometers (OBS) anchored on the sea floor (Fig. 1b); the sea floor provides a quieter environment and data analysis is much simpler if the receiver is fixed. An alternative approach was the “expanded spread profile” (ESP), which involved a shooting ship with explosives or airguns and a receiving ship with a multichannel hydrophone streamer travelling at the same speed on reciprocal courses to maintain a common midpoint. Along with these technical developments came more sophisticated interpretation techniques using synthetic seismograms and waveform inversion. A parallel development was the use during seismic reflection profiling of disposable sonobuoys which transmit the seismic signal by radio back to the shooting ship. By the late 1980s, the data storage capacity of OBHs and OBSs had become sufficiently large that hundreds of closely spaced airgun shots could be recorded, and the use of explosives in marine refraction experiments declined. Recent experiments have used large numbers of OBHs and OBSs laid out in a grid to allow analysis of 3D structures by sophisticated travel-time inversion techniques.

3. Structure of the Oceanic Crust

3.1 *P*-wave Velocity Structure

The basic *P*-wave velocity structure of the oceanic crust was established in the early days of marine geophysics, before the discovery of sea-floor spreading. It was recognised that oceanic crust was thinner than continental crust, and that the same basic structure was present throughout the ocean basins. The average thickness of normal oceanic crust, away from regions considered for various reasons to be anomalous, was found to be about 6.5 km, and this figure has changed little in more recent compilations, despite the use of a variety of different definitions for what is normal oceanic crust. The igneous crust has traditionally been divided into two layers, a 2–3 km Layer 2 and a 3–5 km Layer 3 (e.g., Raitt, 1963), with the overlying sediments labelled as Layer 1, and an underlying mantle layer.

In early compilations the main crustal layers were assigned constant velocities (5.07 ± 0.63 km and 6.69 ± 0.23 for Layer 2 and Layer 3 respectively in Raitt’s compilation), as the data analysis methods available (least-squares slope-intercept solutions for picked first-arrival travel times) did not allow for velocity gradients. However, once synthetic seismogram modelling had come into widespread use (e.g., Spudich and Orcutt, 1980; Fig. 2), it was recognised that the high amplitude signals of Layer 2 corresponded to a high velocity gradient (typically 0.5 – 1.0 sec^{−1}), whereas the lower amplitude signals of Layer 3 corresponded to considerably lower

FIGURE 2 (a) Real and synthetic seismograms for an oceanic crustal site near Guadelupe. The source–receiver range is marked beside each pair of seismograms, and a reduction velocity of 8 km sec^{-1} has been applied (reprinted from Spudich and Orcutt, 1980). (b) Seismic *P*-wave (solid) and *S*-wave (dashed) velocity model corresponding to the synthetic seismograms in (a).

gradients (typically $0.1\text{--}0.2\text{ sec}^{-1}$). Reanalysis of early data by modern synthetic seismogram methods has shown that slope-intercept solutions systematically underestimate oceanic crustal thickness, because the deeper, faster parts of layers are observed only as second arrivals (White *et al.*, 1992).

The Layer 2 and Layer 3 phases are easily recognised on modern record sections from oceanic crust (Fig. 3), which typically show a strong Layer 2 arrival, a weak Layer 3 arrival, a strong Moho reflection and weak mantle arrivals. Both Layer 2 and Layer 3 have also been further subdivided. The terms “Layer 2A” and “Layer 2B” are still commonly used to describe the upper oceanic crust. Layer 2A was defined as a thin layer with low velocities at the top of the crust (Houtz and Ewing, 1976), and Layer 2B was a deeper, higher-velocity layer with high gradients. The structure of Layer 2A appears to vary systematically with age (see Section 4), and variations close to midocean ridge axes have formed a recent focus of attention (see Section 6). Subdivisions of Layer 3 appear to vary between locations.

The geological interpretation of Layers 2 and 3 remains controversial, because direct sampling of the igneous stratigraphy by deep drilling has proved elusive. Based on studies of ophiolites, which are interpreted to be sections of oceanic crust which have been emplaced tectonically onto continents, Layer 2 is commonly identified with extrusive basaltic lavas and a sheeted dyke complex, whereas Layer 3 is identified with intrusive gabbroic rocks. However, many recent studies have emphasised the role of porosity over that of lithology in

the oceanic crust. In the Bay of Islands ophiolite, one of the best-preserved ophiolites, there is an abrupt increase in seismic velocity to $6.7\text{--}6.8\text{ km sec}^{-1}$ at the boundary between brecciated and nonbrecciated dykes, and no sharp increase and the boundary between dykes and gabbros (Fig. 4). This has led many authors to identify the Layer 2/3 boundary with the limit of dyke brecciation. A combination of seismic refraction and downhole logging at ODP Hole 504B on the Costa Rica Rift also shows that the Layer 2/3 boundary occurs within the sheeted dykes (Detrick *et al.*, 1994), though it seems unlikely that the results of Hole 504B can be extrapolated to oceanic crust everywhere.

The significance of the seismic Moho in the oceans, and the composition of Layer 3, have also remained controversial. The recovery of large amounts of serpentinised peridotite by dredging, ODP drilling and submersible diving on the Mid-Atlantic Ridge and other slow-spreading ridges has led some to the suggestion that Layer 3 consists of isolated gabbroic intrusions in serpentinised peridotite and to question the conventional interpretation that the Moho marks a petrological boundary between mafic rocks above and ultramafic rocks beneath (Fig. 5). However, the good agreement between seismically determined crustal thicknesses and geochemically determined melt thicknesses (White *et al.*, 1992), suggests that serpentinised peridotite is not the dominant component in Layer 3 of normal oceanic crust.

3.2 S-wave Velocity Structure

Few data are available on *S*-wave velocities for the oceanic crust and uppermost mantle, and even fewer data are available for the overlying sediment layer. This is because marine seismic sources are commonly within the water column and therefore can only generate *P* waves. *S* waves are only generated if fortuitous mode conversions occur, for example, at the base of the sediment layer. Detectable *S* waves cannot be generated in this way if the sediments are very thick, since then the *S*-wave velocity in the igneous crust is lower than the *P*-wave velocity in the sediments above and therefore any converted *S* waves do not turn within the crust. *S*-wave velocities in oceanic crust are most commonly characterised by Poisson's ratio, which for isotropic rocks is a function of the *P*–*S*-velocity ratio. Poisson's ratio is controlled by lithology, degree of alteration, porosity and the distribution of pore aspect ratios; a value of 0.25 is commonly assumed in crustal rocks where no *S*-wave data are available. Spudich and Orcutt (1980) compared Poisson's ratios derived from synthetic seismogram modelling of converted shear waves in seismic refraction data with measured values from ophiolites and dredge samples to constrain the composition of the oceanic crust. Values of 0.32–0.38 were found in the upper 200 m, indicating the presence of significant fracture porosity which is not present in dredge samples. Anomalously low values of Poisson's ratio (0.22–0.26) are commonly found at around

FIGURE 3 Expanded spread profile 5 from the North Atlantic Transect (reprinted from Mithal and Mutter 1989 with permission from Blackwell Science Ltd). This exceptionally clear record section shows features typical of oceanic crustal structure: high amplitude first arrivals from Layer 2 at 6–11 km range, weaker Layer 3 arrivals at 11–32 km range, a strong postcritical reflection from the Moho labelled IV, weak first arrivals from the mantle at 40–50 km range, and an equivalent set of *S*-wave arrivals. The phase labelled III is a precritical Moho reflection which is rarely seen in wide-angle data from oceanic crust.

FIGURE 4 Lithology and seismic velocities, based on laboratory measurements, of a section through the Bay of Islands ophiolite (simplified from Salisbury and Christensen, 1978).

FIGURE 5 Four possible models of oceanic crustal stratigraphy (reprinted from Minshull *et al.*, 1998 with permission from the Geological Society of London). (a) Layer 3 consists entirely of gabbro. (b) Layer 3 consists entirely of partially serpentinised peridotite. (c) Layer 3 consists of gabbroic intrusions within un-serpentinised to partially serpentinised peridotite. (d) As (c), but the limit of serpentinisation is deeper than the deepest gabbroic intrusion.

1.0–1.5 km depth in oceanic crust, particularly in young oceanic crust. These values might be explained by the presence of thick cracks resulting from hydraulic fracturing of the rock during dyke injection (e.g., Shearer, 1988), or as an artifact of the normal assumption that the crust is isotropic if differing P - and S -wave anisotropy is present (Fryer *et al.*, 1989).

3.3 Anisotropy

Constraints on seismic anisotropy in the oceanic crust are sparse. Since S waves are generally only present if there are fortuitous mode conversions, and coupling problems commonly make S -wave polarisation data unreliable, observations of S -wave splitting at oceanic sites are rare. Early wide-angle seismic experiments (e.g., Shearer and Orcutt, 1985) found a few percent anisotropy in the upper crust for both P and S waves, with a fast direction commonly parallel to the paleo-ridge axis. This anisotropy was attributed to the presence of aligned cracks in the upper crust. Several recent tomographic experiments have also suggested a few percent P -wave anisotropy in the upper 2 km of the crust at ridge axes, but often an isotropic model can also explain observed travel times. Another form of anisotropy which has been suggested for the oceanic crust is one with a horizontal plane of symmetry, arising from a fracture system with a preferred horizontal alignment which would be very hard to detect by conventional seismic experiments. The lower oceanic crust is not thought to be significantly anisotropic because the crack porosity is thought to be greatly reduced by the confining pressure.

3.4 Attenuation

Attenuation is typically quantified as an effective Q value, which includes both intrinsic and scattering attenuation. Scattering attenuation is likely to be the dominant physical process in low porosity, but heterogeneous, oceanic crustal rocks. Most estimates of Q for oceanic crust at seismic frequencies come from reflectivity modelling of high-quality expanding spread profile data, where a 1D assumption is approximately valid. Typical values for P -waves found to be consistent with observed data away from ridge axes are 400 for crustal rocks and 1000 for the uppermost mantle (e.g., Spudich and Orcutt, 1980). These values must be considered to have an uncertainty of at least a factor of two. Laboratory measurements at ultrasonic frequencies have given significantly lower values of less than 100 at all depths except the lower part of Layer 2 (Wepfer and Christensen, 1991).

4. Variation of Crustal Structure with Spreading Rate

The gross thickness of the oceanic crust varies remarkably little with spreading rate (Fig. 6) because of the balance

FIGURE 6 Crustal thickness versus spreading rate for oceanic crust away from the influence of mantle plumes and fracture zones, and omitting anomalous crust adjacent to nonvolcanic passive margins and at extinct spreading centres. Only values constrained by synthetic seismogram modelling or modern 2D travel time inversion techniques are plotted (modified from Bown and White, 1994).

between mantle upwelling rate, which controls the rate of melt production at a midocean ridge, and plate separation rate, which controls the surface area of crust to be created. A slight decrease in crustal thickness, when measurements at fracture zones are excluded, at higher spreading rates may be due to the more efficient distribution of melt along segments at fast-spreading ridges. Most models of melt generation at ridges predict a decrease in crustal thickness at very slow spreading rates. Recent results from the Mohs Ridge (spreading rate $\sim 16 \text{ mm y}^{-1}$) and the Southwest Indian Ridge ($\sim 12\text{--}16 \text{ mm y}^{-1}$) suggest a crustal thickness of $\sim 4 \text{ km}$ and therefore support these models. Crustal thicknesses are generally more variable at slow spreading rates, but most of this variability can be attributed to the effects of ridge segmentation (see Section 7). At extinct rifts such as the Labrador Sea spreading centre, where the spreading rate has slowed to zero, the crust is thinner than normal oceanic crust and is underlain by material with velocities intermediate between Layer 3 velocities and upper mantle velocities, interpreted to be partially serpentinised peridotite. Despite indications from seismic reflection profiles of substantial spreading-rate-controlled differences in the internal architecture of oceanic crust, and differences in composition indicated by geological studies of midocean ridge axes, the seismic velocity structure appears to vary little with spreading rate (e.g., White *et al.*, 1992). At very slow spreading rates, where crustal thickness is reduced, the reduction appears to be predominantly at the expense of Layer 3, as would be expected if the thickness of Layer 2 is determined

predominantly by the porosity and alteration structure of the upper crust.

5. Variation of Crustal Structure with Age

Except in the immediate vicinity of midocean ridge axes (see Section 6), the seismic structure of oceanic crust also varies rather little with age. The dominant age-dependent variation is in the velocity structure of the uppermost crust. Houtz and Ewing (1976) suggested that Layer 2A velocities increased to values typical of Layer 2B (around 5.2 km sec^{-1}) over 30–40 My and its thickness decreased with age, so that Layer 2A gradually disappeared. This systematic variation was attributed to progressive hydrothermal infilling of the upper crustal porosity. More recent analyses suggest that Layer 2A velocities increase rapidly in the first 10 My of evolution and change little thereafter, never reaching Layer 2B values and that there is no systematic variation in Layer 2A thickness with age (e.g., Grevemeyer *et al.*, 1998).

6. Seismic Structure of the Moho and Uppermost Oceanic Mantle

Reflections from the Moho are often strong and continuous in wide-angle record sections from normal oceanic crust (e.g., Fig. 3), suggesting a transition from crustal velocities of around $6.8\text{--}7.2 \text{ km sec}^{-1}$ to upper mantle velocities of around 8 km sec^{-1} over a depth interval which is short compared to seismic wavelengths. However, in seismic reflection data the Moho reflection is often discontinuous, and observations from ophiolites suggest that the crust–mantle transition may sometimes occur over an interval of several kilometres in which the ultramafic content increases with depth. Such transition zones may be spatially localized and therefore not resolved by the wide-angle survey geometries commonly used prior to the 1990s. Mantle arrivals are commonly weak in airgun refraction experiments from oceanic crust (e.g., Fig. 3). Where good constraints are available, the *P*-wave velocity of the uppermost mantle in mature oceanic crust varies little from an average of 8.0 km sec^{-1} , though some azimuthal variation due to preferential alignment of olivine crystals has been observed (e.g., Shearer and Orcutt, 1985). The low *Pn* amplitudes suggest the velocity gradient in the uppermost mantle is very low. Lower velocities have been measured close to ridge axes; for example, velocities appear to increase from around 7.5 km sec^{-1} at the axis of the East Pacific Rise to around $8.0\text{--}8.2 \text{ km sec}^{-1}$ over a period of a few millions years (e.g., Grevemeyer *et al.*, 1998). Upper mantle *S* wave arrivals are even more rare in marine refraction data; however, the

sparse data available are consistent with an *S*-wave velocity of around 4.6 km sec^{-1} and a Poisson's ratio of 0.25.

7. Crustal Structure of Midocean Ridges

7.1 Fast-spreading Ridges

Over the last decade, the seismic velocity structure of the fast-spreading East Pacific Rise has been intensely studied. A localised low velocity zone, interpreted as resulting from the presence of a magma chamber containing molten or partially molten rock, was first detected on the northern East Pacific Rise by OBS refraction experiments in the 1970s. Subsequent ESPs and seismic tomography experiments (e.g., Toomey *et al.*, 1990) have indicated that the low-velocity zone extends from 1–2 km below the seabed to the base of the crust, and increases in width from $\sim 2 \text{ km}$ wide at its top to 10–12 km near the Moho (Fig. 7a). The lowest velocities (below 5 km sec^{-1}), attributed to the presence of melt, were constrained by these data to lie within a zone less than 1 km thick about 2 km beneath the rise axis, whereas below this region velocities were found to be considerably higher, though still up to 1 km sec^{-1} below normal Layer 3 velocities. OBS experiments have also suggested the presence of a several-kilometer-thick low-velocity zone immediately beneath the crust, also interpreted as due to the presence of partial melt. A limitation in the interpretation of these results is that there are few good laboratory studies of the elastic properties of partially molten basalt, and these studies have contradictory results about how seismic velocities vary close to the solidus. Multichannel seismic reflection techniques have demonstrated the presence of a high-amplitude and continuous reflector along large sections of the East Pacific Rise. Synthetic seismogram modelling and waveform inversion studies of this reflector have indicated that it consists of a thin lens ($<100 \text{ m}$) of molten rock with a width varying from around 250 m to 4 km.

Based on multichannel reflection and bottom shot experiments, the structure of the upper few hundred meters of the crust at the East Pacific Rise axis appears to vary remarkably little along strike, with a $<100 \text{ m}$ thick zone where the velocity is around 2.5 km sec^{-1} and the velocity gradient is very low, underlain by a 100–200 m zone where the velocity increases sharply to around 5.0 km sec^{-1} , underlain by a shallower gradient again. At ridge axes, the term “Layer 2A” is commonly applied to the low-gradient zone near the seabed and the steep gradient zone beneath it. This gradient is sufficiently steep to generate wide-angle reflections in multichannel reflection data, which have allowed the layer thickness to be mapped along large regions of the East Pacific Rise. These studies have shown that Layer 2A is 100–300 m thick on-axis, and doubles in thickness within 1–4 km of the rise axis (e.g., Christesen *et al.*, 1994). Layer 2A is generally interpreted as

FIGURE 7 (a) *P*-wave velocity model and interpretation, based on expanding spread profile and multichannel reflection data, of the fast-spreading East Pacific Rise axis at 9° N. Arrows mark ESP locations (redrawn from Vera *et al.*, 1990). (b) *P*-wave velocity model and interpretation, based on OBS and seismic reflection data, of the slow-spreading Reykjanes Ridge axis at 57°45' N. Triangles mark OBS locations and dashed lines mark changes in velocity gradient (redrawn from Navin *et al.*, 1998 with permission from Blackwell Science Ltd).

the extrusive layer at fast-spreading ridges, with the steep velocity gradient at its base corresponding to a transition to lower-porosity sheeted dikes, and off-axis thickening resulting from further accumulation of lava flows.

7.2 Intermediate-spreading Ridges

There have been many fewer seismic studies of intermediate-spreading ridges. A seismic reflection survey of the back-arc

Valu Fa spreading centre found a widespread, high amplitude reflector at a depth of around 3.2 km with a width of 0.6–4 km (Collier and Sinha, 1992). The reflection coefficient for this event corresponds to a *P*-wave velocity of less than 3.8 km sec⁻¹, and coincident wide-angle seismic data indicate the presence of a low-velocity zone, so the reflector is interpreted as marking the top of a crustal magma chamber which is significantly deeper than the magma chamber on the East Pacific Rise. OBH studies conducted on various parts of the

Juan de Fuca Ridge have not found convincing evidence for a crustal magma chamber, but have found a seismic Layer 2A similar to that found on the East Pacific Rise, with an abrupt doubling of P -wave velocity at 0.25–0.60 km below the seabed. Layer 2A is thinnest at the ridge axis, but off-axis the thickness varies irregularly, perhaps due to an episodic form of magmatism, with tectonic rotations occurring between magmatic episodes.

7.3 Slow-spreading Ridges

Early OBS refraction experiments on the Mid-Atlantic Ridge found neither a low-velocity zone corresponding to a magma chamber, nor a strong velocity contrast at Moho depths; rather, the crust–mantle transition was characterised by a gradual increase in velocities. However, modern experiments have found clear Moho reflections corresponding to a more abrupt step in velocity, and a detailed tomographic study focused on the upper crust at 35° N (Barclay *et al.*, 1998) found a zone of anomalously low velocities immediately beneath the seabed with a width of about 2 km and a depth extent of about 1 km, interpreted as due to near-solidus temperatures or possibly the presence of partial melt. To date, the most convincing seismic evidence for a magma chamber at a slow-spreading ridge comes from an experiment at 57°40' N on the Reykjanes Ridge (Fig. 7b). Here, a high-amplitude, reversed polarity reflection was imaged in low-fold reflection data and a low-velocity zone is required to match shadow zones seen in wide-angle seismic data. The dimensions of the low-velocity zone are weakly constrained, but the data are consistent with a thin lens of low-velocity material between 2 and 3 km depth. Seabed velocities at slow-spreading ridge axes appear to be around 2.5 km sec^{-1} , similar to those at faster spreading rates, indicating similar porosities at the ridge axis. However, Layer 2A does not appear to be significantly thinner on-axis than immediately off-axis; accretion of the uppermost crust on slow-spreading ridges is a more irregular process, and Layer 2A may not be equivalent to the extrusive section.

8. Crustal Structure at Oceanic Fracture Zones and Segment Boundaries

8.1 Segmentation of Slow-spreading Ridges

Several major studies of large-offset Atlantic fracture zones showed that they are characterised by anomalously thin crust and anomalously low seismic velocities (Fig. 8a). Fracture zone crustal structures generally fall between two end-members, referred to as “type A” and “type B” by Sinha and Loudon (1983); both types of crust have been found at several large-offset Atlantic fracture zones. Type A crust is typically 4–5 km thick and characterised by lower seismic velocities than normal

FIGURE 8 Seismic velocity structure of oceanic fracture zones at slow-spreading ridges. (a) A large-offset fracture zone: the Charlie-Gibbs Fracture Zone. OBS locations are marked at the top of the figure and rays traced to shot positions (redrawn from Whitmarsh and Calvert, 1986, with permission from Blackwell Science Ltd). (b) A small-offset fracture zone: the Blake Spur Fracture Zone. Arrowheads mark ESP locations (redrawn from Minshull *et al.*, 1991).

for oceanic crust, particularly at lower crustal depths. Type B crust is less than 3 km thick and has a velocity structure that is fundamentally different from normal oceanic crust. Typically, velocities in the uppermost crust are anomalously low, and the velocity gradient is high throughout the crustal section. The low upper crustal velocities have been attributed to highly fractured basaltic and possibly gabbroic material, though serpentinite has been dredged frequently in fracture zone valleys and must be present in the upper crust of the valley walls and/or floor. Another common feature is the presence of velocities in the range $7.2\text{--}7.5 \text{ km sec}^{-1}$, intermediate between normal oceanic crust and upper mantle velocities, interpreted as due to the presence of serpentinised upper mantle at the base of the crust. Seismic experiments have shown large along-axis variations in crustal thickness even where the offset in the ridge axis is relatively small (Fig. 8b). In addition to the dramatic changes in crustal structure which occur toward segment ends,

some experiments have also shown a steady increase in crustal thickness to anomalously large values of 8–10 km toward segment centres.

8.2 Segmentation of Fast-spreading Ridges

The only fracture zone on the East Pacific Rise which has been studied in some detail is the Clipperton Fracture Zone (Begnaud *et al.*, 1997), with an age offset of 1.5 My, similar to that of small-offset transforms and nontransform discontinuities in the Atlantic. Here, there is no apparent crustal thinning at the fracture zone. Rather, the crustal thickness is normal in the active transform valley and the crust is slightly thickened at the ridge–transform intersection, where the addition of extrusive material from the adjacent spreading centre results in a local bathymetric high. Both in the active transform and at the ridge–transform intersection, seismic velocities are lower throughout the crust than in the adjacent oceanic crust. The reduced velocities are attributed to enhanced fracturing associated with the strike-slip motion.

9. Hotspots, Ocean Islands, Aseismic Ridges and Oceanic Plateaux

The majority of crustal thickness variations in the oceans which cannot be attributed to the effects of ridge axis segmentation are attributed to the influence of so-called “hotspots.” Hotspots take a variety of forms, but are generally thought to be associated with anomalies in mantle temperature and/or chemistry due to anomalous material rising from deep in the mantle.

9.1 Ridge–hotspot Interactions

Hotspots have their greatest effect on crustal structure when they are located at or near a midocean ridge. The clearest and best-studied example is the Iceland hotspot, which thickens the crust sufficiently to lift the spreading centre above sea level. The thickness of the crust in Iceland was thought for many years to be only around 10–15 km, but a series of recent refraction experiments has shown that the crustal thickness varies between 20 and 40 km, and is greatest at the inferred present-day location of the hotspot. The upper crust in Iceland has velocities increasing from about 3.2 km sec^{-1} at the top to about 6.4 km sec^{-1} at the base. The thickness of the upper crust varies between about 2 km and 10 km, and reaches a minimum beneath central volcanoes (Fig. 9). The Icelandic lower crust has a smooth gradient between about 6.4 km sec^{-1} and $7.2\text{--}7.35 \text{ km sec}^{-1}$ and a thickness varying between 10 and 30 km. Dramatic variations in crustal thickness may result from a history of ridge jumps as well as from variations in

FIGURE 9 Seismic velocity structure of Icelandic crust (redrawn from Darbyshire *et al.*, 1998 with permission from Blackwell Science Ltd). (a) Seismic velocity model across the Northern Volcanic Zone in northeast Iceland; (b) seismic velocity model across the Eastern Volcanic Zone in southeast Iceland.

proximity to the core of the inferred underlying mantle plume. In contrast to the elusive evidence for crustal melt bodies elsewhere on slow-spreading ridge axes, several such melt bodies have been detected seismically in Iceland. For example, a low-velocity zone detected beneath Krafla central volcano in northeast Iceland and inferred to represent a magma chamber has horizontal dimensions of 2–3 km by 8–10 km and a thickness of 0.75–1.8 km, and its top lies at about 3 km depth (Brandsdóttir *et al.*, 1997).

9.2 Aseismic Ridges and Oceanic Plateaux

Aseismic ridges are thought to mark the off-axis trace of ridge-centred hotspots which have stayed close to the spreading centre. Some of these ridges probably have been subaerial for much of their history, and therefore have had their upper parts removed by erosion. The most prominent aseismic ridges, such as the Madagascar Ridge, have crustal thicknesses of up to 25–30 km (Fig. 10a). Other less-prominent features such as the Madeira-Tore Rise in the central Atlantic have crustal thicknesses of 10–15 km (Fig. 10a). The high-gradient upper crust at these ridges is only slightly thicker than oceanic Layer 2, at typically $\sim 4 \text{ km}$, whereas the underlying low-gradient layer is much thicker than normal oceanic Layer 3.

FIGURE 10 Crustal structure of aseismic ridges and oceanic plateaux. (a) Madagascar Ridge (Sinha *et al.*, 1981), Madeira-Tore Rise (Peirce and Barton, 1991), Azores-Biscay Rise (Whitmarsh *et al.*, 1982). (b) Crustal structure of northern Kerguelen plateau compared with Iceland (redrawn from Operto and Charvis, 1996). (c) Crustal structure of southern Kerguelen plateau compared with the Hatton Bank rifted margin (redrawn from Operto and Chavis, 1996).

Anomalously high velocities of $7.2\text{--}7.5\text{ km sec}^{-1}$, interpreted as due to a high magnesium content of the igneous material, have been detected along some aseismic ridges. Oceanic plateaux represent vast outpourings of magma which may also result from near-ridge hotspot activity, but on a larger scale than for aseismic ridges. A type example is the Kerguelen Plateau in the southern Indian Ocean. The southern part of Kerguelen Plateau has recently been interpreted as a stretched continental fragment, and its velocity structure is very similar to that of volcanic rifted margins (Fig. 10c). The northern Kerguelen Plateau is interpreted to be purely oceanic and has a 20–22 km thick crust with a very thick, low-velocity gradient lower crust; the overall structure is very similar to that of southwest Iceland (Fig. 10b). The Kerguelen Isles themselves appear to have a structure which closely resembles that of large oceanic intraplate volcanoes (see Section 9.3).

9.3 Oceanic Intraplate Volcanism

Oceanic intraplate volcanism takes place on a variety of scales, from large islands such as La Reunion to the very many small seamounts which dot the ocean floor. The most well-known example is the Hawaiian chain, where the motion of an underlying mantle plume relative to the overlying Pacific plate is clearly marked by a linear chain of islands and seamounts. Seismic experiments at islands and seamounts have commonly focused on quantifying the deformation of the underlying lithosphere in response to the volcanic load. These experiments

have confirmed the suggestion based on gravity studies that there is commonly a depression of both the top of the oceanic crust and the Moho (Fig. 11), and also shown the presence of a high-velocity basal layer attributed to underplated basaltic melt. The significance of underplating remains controversial. The results of an experiment close to the Hawaiian Island of Oahu, were initially interpreted to indicate an underplated body 3–6 km thick (Fig. 11a), but later the same data were reinterpreted to suggest that no underplated body was present. An experiment around the Canary island of Tenerife found no evidence for underplating (Fig. 11b), but a thick underplated body has been inferred beneath the Marquesas Islands (Fig. 11c).

Rather little is known about the internal velocity structure of ocean islands. The basic picture which emerges from seismic experiments is of a central high-velocity core, which probably consists primarily of intrusive rocks, and an outer shell of lower velocity material consisting primarily of lava flows, pyroclastic deposits and the products of mass wasting. Ocean islands often have multiple rift zones cored by high-velocity intrusives, but such detailed structure is rarely resolved by seismic data. Good constraints have been obtained for a few oceanic intraplate volcanoes which are entirely submarine; these data suggest that small volcanic edifices contain a much larger proportion of low-velocity materials than their larger counterparts. On the island of Hawaii, an intensive effort using mainly passive seismic techniques has allowed the detailed structure of the crustal magma body supplying the main active volcanoes, Mauna Loa and Kilauea, to be imaged (e.g., Ryan, 1988).

10. Passive Margins and Ocean–Continent Transitions

Passive continental margins may be divided into rifted margins, where the direction of extension is approximately perpendicular to the resulting margin; and transform margins, where the relative plate motion was along the margin. Rifted margins have been further divided into “volcanic” margins, where there is extensive evidence for syn-rift magmatism, and “non-volcanic” margins, where syn-rift magmatism is weak or absent. The origin of this variation remains controversial: some authors have emphasised the role of the temperature of the underlying mantle, whereas others have emphasised the role of small-scale convective circulation in the mantle in generating volcanic margins.

10.1 Volcanic Rifted Margins

Of the three categories described above, volcanic rifted margins may be the most abundant and are certainly the best studied. Two main seismic characteristics have been identified. Firstly, distinctive arcuate seaward dipping reflectors are observed in seismic reflection profiles, confirmed by ODP drilling to be the result of the impedance contrasts between successive subaerial basalt flows. Secondly, volcanic margins are characterised by the presence of a thick wedge of high-velocity material at the base of the thinned continental crust, interpreted as the result of mafic underplating during continental breakup. In the northeast Atlantic, the thickness of this wedge varies systematically along the margin, with the thickest underplating in the vicinity of the inferred location of the Iceland plume at breakup time and thinner underplates in more distal regions (Fig. 12). This systematic variation provides strong evidence for a mantle plume control on the degree of magmatism, but is not seen in the other well-studied group of nonvolcanic margins, off the east coast of the United States of America. At volcanic margins, the transition to oceanic crust is fairly abrupt, and any transition zone is inferred to be the result of intense magmatic intrusion of the thinned continental crust, since seismic velocities are intermediate between those of the thinned continental crust and those of the adjacent oceanic crust. The first-formed oceanic crust seaward of the volcanic margins is also often anomalously thick.

10.2 Nonvolcanic Rifted Margins

Until recently, nonvolcanic rifted margins were thought to be typified by seismic velocity structures such as that inferred for the Goban Spur margin (Fig. 13a): continental crust thins from a full thickness of around 30 km to a thickness of 5–6 km, and adjacent to this lies a slightly thin oceanic crust with a velocity structure very similar to normal oceanic crust. However, several recent seismic refraction experiments, with

FIGURE 12 Seismic velocity models for volcanic continental margins off northwest Europe. Cross-hatching shows areas where seaward-dipping reflectors, interpreted as lava flows, have been imaged in seismic reflection profiles, and shaded regions are high-velocity lower crustal bodies interpreted as underplated igneous material [reprinted from Richardson *et al.* (1998). Copyright 1998, with permission from Elsevier Science].

a large number of closely spaced receivers to define the velocity structure in much greater detail, have detected a broad “transition zone” between thinned continental crust and unequivocal oceanic crust with an anomalous velocity structure which cannot be interpreted as the result of mafic intrusion of continental crust. This transition zone typically has low velocities in the upper part of the basement and high velocities (in the range $7.2\text{--}8\text{ km sec}^{-1}$) at depths of 3–5 km (Fig. 13b). In this case the high basal velocities are commonly interpreted as due to partial serpentinisation of the uppermost mantle. Seismic reflection profiling at nonvolcanic margins has revealed much about the way the continental lithosphere deforms during the final stages of continental breakup. Tilted basement blocks overlain by wedges of synrift sediments are commonly observed; on some margins the faults bounding these blocks are also imaged, and these faults appear to sole out into a low-angle detachment fault marked by a high-amplitude subhorizontal reflector (e.g., Reston *et al.*, 1996).

10.3 Transform Margins

In contrast to rifted margins, transform margins have received rather little attention from seismic experiments. A detailed study of the southern Exmouth Plateau transform margin off northwest Australia found a thick high-velocity body is present at the base of the crust which resembles the mafic underplating observed at volcanic rifted margins. However, other studies at transform margins have not found underplated bodies, and instead have found a narrow zone of rather thin crust adjacent to the continent (e.g., Edwards *et al.*, 1997). In some cases this thin crust has high velocities at its base, and these velocities are interpreted as due to the presence of partially serpentinised mantle in an analogy to oceanic fracture zones.

11. Concluding Remarks

Modern marine seismic experiments are complex and very expensive operations, increasingly difficult to justify in a world of intense competition for research funds. The reconnaissance work of the 1950s to 1970s gave us our basic knowledge of the thickness and seismic structure of oceanic crust, but most profiles were acquired without an understanding of their plate tectonic setting, methods of analysis were limited, and spatial sampling was not sufficient to resolve subtle lateral variations which are now considered to be important. The more sophisticated experiments of the last two decades have provided us with insights into the fundamental processes which cause variations in the seismic velocity structure of the ocean basins, but by any standard the sampling of oceanic structure remains sparse, and heavily concentrated in the North Atlantic and northeast Pacific. Our view of what is typical may well be changed in the future by more extensive exploration of the

FIGURE 13 Seismic velocity models for nonvolcanic continental margins. (a) The Goban spur margin, with no interpreted ocean–continent transition zone [redrawn from Horsefield *et al.* (1993) with permission from Blackwell Science Ltd]. (b) Conjugate margins of the Labrador Sea (redrawn from Chian *et al.*, 1995). Here, zone 1 is thinned continental crust, zone 2 is the transition zone and zone 3 is oceanic crust.

Arctic Ocean, the South Atlantic, the Indian Ocean basins, the Southern Ocean, the southwest Pacific and the margins of these oceans. Even in the North Atlantic, it is clear that finer-scale sampling of the seismic structure is required to fully understand the complexities revealed by geological sampling of the ridge axis.

The Earth's Core

Xiaodong Song

University of Illinois, Urbana, IL, USA

1. Introduction

The purpose of this chapter is to present a brief review of our basic understanding of the Earth's core, which was acquired almost entirely during the 20th century. The Earth's core plays an important role in the formation and chemical differentiation of our planet, in global earth dynamics and earth rotation, and in the generation of the magnetic field (see Table 1 for a summary of our most basic knowledge about the core).

The review emphasizes seismological accomplishments. For in-depth discussions on various aspects of core studies, see previous reviews on seismology (Bolt, 1987; Masters, 1991; Tromp, 1995a; Song, 1997; Creager, 2000; Richards, 2000; Romanowicz and Durek, 2000), mineral physics (Jeanloz, 1990; Boehler, 1996; Stixrude and Brown, 1998), core formation (Ringwood, 1984; Jones and Drake, 1986; Jacobs, 1987; Stevenson, 1987; Labrosse *et al.*, 1997), light elements in the core (Jeanloz, 1990; Poirier, 1994a; Allègre *et al.*, 1995), physical properties of the core (Poirier, 1994b; Anderson, 1995; Braginsky and Roberts, 1995), core dynamics (Glatzmaier and Roberts, 1998; Buffett, 2000), and core–mantle boundary (CMB), and core–mantle interactions (Young and Lay, 1987; Lay *et al.*, 1998; and Chapter 51 by T. Lay).

2. Discovery of the Earth's Core

The discovery of the Earth's core was contemporaneous with the birth of modern instrumental seismology in the early part of the 20th century. An elegant account of the discovery and characterization of the Earth's core was presented in a historical memoir by Brush (1980).

In 1896 Wiechert proposed a two-layered model of the Earth with an iron core and a stony shell, inferred from the Earth's rotation and gravity. He argued that a difference in chemical composition in the Earth's interior is required to explain the difference, by a factor of two, between the average density of the Earth and the density of rocks near the surface. The direct evidence for the Earth's core came from seismology in 1906 when Oldham (1906) observed abrupt changes in *P* and *S* velocities beyond about 120°. He postulated that a low-velocity region in the interior, the central core, produced a shadow zone. Gutenberg (1913) accurately estimated a depth to the core of 2900 km in 1912 from *P*-wave travel times. By 1926 Jeffreys had showed that the combination of tidal deformation and the rigidity of the mantle inferred from seismic velocities implies a low rigidity (possibly zero) in the central core. A liquid core explains the absence of observable *S* waves traversing the core.

TABLE 1 A Summary of the Earth's Core

- The Earth's core was formed very early in Earth's history as heavy molten iron alloy migrated toward the center of the planet. High temperatures (~5000 K) keep the bulk of the core liquid.
- As the Earth cooled and dissipated its internal heat toward the surface through mantle convection, molten iron began to solidify under enormous pressure (over 3 Mbar) to form the solid inner core.
- The fluid outer core is predominantly iron but cannot be purely iron; the inner core is almost pure iron.
- The size of the outer core is more than a half of the Earth in radius. The size of inner core is about one fifth of the Earth in radius and slightly smaller than the moon.
- The Earth's core was discovered by Oldham in 1906 and the inner core was discovered by Lehmann in 1936 using seismic waves.
- Jeffreys proved the outer core is liquid in 1926 and Dziewonski and Gilbert proved the inner core is solid in 1971.
- The gravitational energy release from the slow growth of the inner core as the liquid iron freezes drives the convection in the outer core which generates the Earth's magnetic field.
- The inner core is elastically anisotropic with the fast direction approximately parallel to the spin axis. The anisotropy comes from preferred alignment of iron crystals in the inner core.
- The inner core is suggested to be rotating faster than the mantle at a fraction of a degree per year.

TABLE 2 Notation Used for Seismic Core Phases

Notation	Description
<i>P</i>	Compressional wave in the mantle or compressional wave in general
<i>S</i>	Shear wave in the mantle or shear wave in general
<i>K</i>	Compressional wave in the core (after “Kern,” a German word meaning core)
<i>I</i>	Compressional wave in the inner core
<i>J</i>	Shear wave in the inner core
<i>c</i>	Topside reflection from the core–mantle boundary
<i>i</i>	Topside reflection from the inner core boundary
<i>PcP</i>	Compressional wave reflected from the core–mantle boundary
<i>ScS</i>	Shear wave reflected from the core–mantle boundary
<i>PKP</i> or <i>P'</i>	Travelling from the source through the mantle, entering the core, and coming back up through the mantle again to the station at the Earth’s surface all as compressional wave
<i>PKP(AB)</i>	A branch (AB) of <i>PKP</i> that turns in midouter core
<i>PKP(BC)</i>	A branch (BC) of <i>PKP</i> that turns near the bottom of the outer core
<i>PKP(CD)</i> or <i>PKiKP</i>	A branch (CD) of <i>PKP</i> that is reflected from the inner core boundary
<i>PKP(DF)</i> or <i>PKIKP</i>	A branch (DF) of <i>PKP</i> that transverses the inner core as compressional wave
<i>PmKP</i>	Short hand for <i>PKP</i> multiples (<i>PKP</i> , <i>PKKP</i> , <i>PKKKP</i> , etc.). As an example, <i>PKKP</i> has one underside (i.e., internal) reflection at the core–mantle boundary (<i>K</i> -to- <i>K</i>).
<i>PKJKP</i>	Compressional wave that converts to shear wave from the outer core to the inner core that converts back to compressional wave as it re-enters the outer core
<i>PKIKP</i>	One underside reflection from <i>I</i> to <i>I</i> at the inner core boundary
<i>SKS</i>	Shear wave through the mantle, compressional wave through the core, and shear wave back up through the mantle
<i>SmKS</i>	Short hand for <i>SKS</i> multiple (<i>SKS</i> , <i>SKKS</i> , <i>SKKKS</i> , etc.).

The inner core was hypothesized by Lehmann in 1936 from the presence of waves in the core shadow zone. The waves (*P'*, to denote the compressional waves that pass through the mantle and the core) could not be explained by the alternative explanation of diffraction. See Table 2 for the notation used for selected seismic core phases and Figure 1 for their ray paths. Assuming a simplified model with constant velocities in the mantle, outer core, and the inner core, she inferred the radius and the velocity of the inner core that explained the observed *P'* travel times reasonably well.

Birch (1940) conjectured that the inner core might be solid; it might simply be a solidified phase of iron. Bullen (1946) argued that the inner core must be solid from the marked increase of *P* velocities across the inner-core boundary (ICB). The *P* velocity $V_P = [(K + 4/3\mu)/\rho]^{1/2}$, where *K*, μ , and ρ are bulk modulus, shear modulus, and density, respectively. Since $\mu = 0$ in the outer core and ρ would not decrease with depth and *K* would change only slowly at high

FIGURE 1 Ray paths of selected seismic phases. The three circles represent the surface, the core–mantle boundary, and the inner core boundary, respectively. The solid segments of the ray paths represent compressional waves and the dashed segments represent shear waves. See also Table 2 for notation of the phases.

pressures, the only plausible way to increase V_P markedly is to give μ in the inner core a finite value. It was not until the beginning of 1970s that solidity of the inner core was demonstrated by the existence of finite rigidity affecting the periods of core-sensitive normal modes (Dziewonski and Gilbert, 1971). The more recent discovery that the inner core is anisotropic (see discussion below) also requires finite rigidity in the inner core.

3. Composition

The distinct difference in composition between meteorites and rocks from the Earth’s mantle virtually requires a major repository for iron and nickel, i.e., in the Earth’s core. Using sound velocity and density measurements obtained from shock-wave experiments for various elements, Birch (1961, 1964) conclusively showed that iron is the only element compatible with the density and pressure of the core. The idea that the Earth’s core consists mainly of iron and nickel alloys has since been well accepted. On the basis of cosmic abundances, the nickel content of the core is a few percent of the iron content. However, the Earth’s core cannot be made of pure iron based on the comparison of the density and sound velocity determined from seismology with laboratory measurements and the equation of

state for pure iron. The outer core is about 10% less dense than pure iron at the core conditions, requiring the presence of one or more light elements in the outer core (Birch, 1952). The nature and proportions of these light elements have been the subject of an ongoing active debate (e.g., Brett, 1976; Stevenson, 1981; Jacobs, 1987, 1992; Ringwood, 1984; Jeanloz, 1990; Wood, 1993; Poirier, 1994a,b; Allègre *et al.*, 1995). Possible light elements include Si, S, O, H, and C. Two major considerations on the choice of light element are cosmic abundances and metallurgical constraints. The nature of the light elements in the core has important implications for the temperature profile in the core, for the compositional convection in the outer core (which is thought to drive the geodynamo), and for the formation and evolution of the core.

In contrast with the outer core, the elastic properties and density of the inner core determined from seismology are consistent with those of pure solid iron with some nickel (and perhaps with some, but much smaller, amount of light elements) (e.g., Anderson, 1986; Jephcoat and Olson, 1987; Stixrude *et al.*, 1997).

4. Earth's Core and Geodynamo

It was long ago recognized that the Earth is magnetic. For example, the first compass was invented in China two thousand years ago (Needham, 1962). However, the origin of the Earth's magnetic field had not been convincingly explained until the 20th century [see review by Glatzmaier and Roberts (1998)]. The seismological discovery of the fluid core (Oldham, 1906) marked a key turning point in the understanding of the origin of the geomagnetic field. The combination of fluidity and electrical conductivity soon allowed Larmor (1919) to propose that the Earth's magnetic field is generated by fluid motions in the core through self-excited dynamo action. The concept of a geodynamo is well accepted today, notably through pioneering work by Elsasser, Bullard, and others in 1940s and 1950s.

The dynamo problem is notoriously difficult, partly due to the famous Cowling (1934) theorem, which states that an axisymmetric magnetic field cannot be maintained by a symmetric motion. Therefore, any realistic dynamo model has to be 3D, a task far more difficult to handle. Nevertheless, thanks to the rapid advancement of computer technology, numerical simulations of self-consistent 3D models of the geodynamo have been obtained (Glatzmaier and Roberts, 1995a; Kuang and Bloxham, 1997). The magnetic field produced possesses several features resembling the geomagnetic field. Most remarkably, geodynamo simulations containing a finite conducting inner core have been shown to undergo a magnetic reversal (Glatzmaier and Roberts, 1995a,b), similar to those observed in the geomagnetic field over the Earth's history. The Glatzmaier and Roberts (1995a) dynamo also predicted a fast

superrotation of the inner core, which was later observed by seismology (see below).

Despite its small size compared to the outer core, the inner core plays a role in the geodynamo. The favored source of energy for driving the geodynamo is the gravitational energy derived from the release of light constituents as the liquid iron freezes to form the solid inner core (Braginsky, 1963; Gubbins, 1977; Loper and Roberts, 1978; Loper, 1978; Lister and Buffett, 1995). The solid inner core has been shown to stabilize the dynamo and establish a constant polarity of the field such as is found on the Earth (Hollerbach and Jones, 1993; Glatzmaier and Roberts, 1995a; Sakuraba and Kono, 1999).

5. Outer Core Structure

Due to its vigorous convection, the liquid outer core is generally considered to be laterally homogeneous in density and seismic velocity (Stevenson, 1987), except perhaps near the boundaries (Wahr and de Vries, 1989). By 1939, Jeffreys (1939a,b) had developed a velocity model, which is still used as a standard reference today [known as the J-B table from a later summary by Jeffreys and Bullen (1940)]. The difference in *P*-wave velocity in the bulk of the outer core between the Jeffreys's model and models proposed later is quite small (within about 1%). The main areas of contention are near the boundaries (the ICB and the CMB) (e.g., see a comparison of *P*-velocity models in Song and Helmberger, 1992).

The nature of the ICB has been one of the main topics since the discovery of the inner core in 1936. The key issues include the sharpness of the boundary, the velocity and density jump at the boundary, the velocity gradient above and below the boundary, and the *Q* structure near the boundary (e.g., Bolt, 1987; Cummins and Johnson, 1988; Song and Helmberger, 1992). The inner core appears sharp since short-period (1 sec) vertical reflections from the boundary *PKiKP* can clearly be observed (Engdahl *et al.*, 1970). These short-period *PKiKP* reflections provide excellent observations for estimating the inner-core radius (Engdahl *et al.*, 1970, 1974) and for estimating the density jump at the ICB (using *PKiKP/PcP* ratios) (Bolt and Qamar, 1970; Bolt, 1972; Souriau and Souriau, 1989; Shearer and Masters, 1990). Observations of *PKP* travel times and waveforms seem to suggest a low to zero velocity gradient at the base of the fluid core (Souriau and Poupinet, 1991; Song and Helmberger, 1992, 1995a,b; Kennett *et al.*, 1995). Such a low velocity gradient implies inhomogeneity at the base of the fluid core (Song and Helmberger, 1995a,b). A transition zone structure at the base of the fluid core with distinct discontinuity about 420 km above the ICB (the so-called F layer) was proposed (Bolt, 1962, 1964) to explain short-period precursors to *PKP* at distances near 130°. The idea of a distinct discontinuity in the fluid core is now generally discarded and the *PKP*

precursors have been successfully interpreted as scattering from the lowermost mantle region (Cleary and Haddon, 1972; Haddon and Cleary, 1973, 1974) or perhaps from the whole mantle (Hedlin *et al.*, 1997).

The light elements released from the compositional convection driven by the crystallization of the solid inner core may form a low-density layer at the top of the outer core (Braginsky, 1963; Fearn and Loper, 1981; Lister and Buffett, 1998; Braginsky, 1999), which has consequences for the core convection and the geodynamo (Bloxxham, 1990). Seismological evidence for such a stably stratified layer has been reported but remains inconclusive (Lay and Young, 1990; Souriau and Poupinet, 1990, 1991; Kohler and Tanimoto, 1992; Tanaka and Hamaguchi, 1993; Garnero *et al.*, 1993; Garnero and Helmberger, 1994; Garnero and Lay, 1998). Because of the sharp decrease in P velocity from the mantle to the core, the only seismic phases with ray paths bottoming the outermost 200 km of the core are the suite of $SmKS$ (SKS , $SKKS$, etc.). Studies of the outermost outer core rely on differential SKS times ($SKKS-SKS$, etc.), which reduces biases from upper mantle heterogeneity. However, SKS differential times are still subject to strong lateral variations on the mantle side of the CMB, making inferences on core-side structure difficult.

The quality factor Q of the outer core is apparently extremely high since high-frequency $PmKP$ phases (up to $P7KP$) are observable (Qamar and Eisenberg, 1974). The Q_α in the outer core is at least several to ten thousand and probably higher from spectral ratios of seismic core phases (Buchbinder, 1972; Sacks, 1972; Qamar and Eisenberg, 1974; Cormier and Richards, 1976; Tanaka and Hamaguchi, 1996).

6. Inner Core Structure

Discovered by Lehmann (1936), the inner core has turned up a number of surprises in recent years: it is anisotropic, it stabilizes the Earth's magnetic field, it is rotating relative to the mantle, it is layered, and it is strongly heterogeneous.

6.1 Inner Core Anisotropy

The first evidence for strong aspherical structure within the core came from anomalous splitting (not explainable simply by Coriolis and ellipticity effects) of the normal modes (Masters and Gilbert, 1981), and anomalous $PKiKP$ arrival times from the International Seismological Centre (ISC) Bulletins (Poupinet *et al.*, 1983). Anisotropy of the inner core was first proposed in 1986 to explain observations of ISC arrival time anomalies (Morelli *et al.*, 1986) and anomalous normal mode splitting (Woodhouse *et al.*, 1986). Morelli *et al.* (1986) and Woodhouse *et al.* (1986) hypothesized that the inner core is anisotropic with cylindrical symmetry around the Earth's spin axis.

By the mid-1990s, the presence of significant anisotropy in the inner core was well established with evidence from both travel time studies (Creager, 1992; Song and Helmberger, 1993; Shearer, 1994) and normal mode data (Tromp, 1993, 1995b,c). The anisotropy appears to be dominated by cylindrical anisotropy with the axis of symmetry aligned approximately with the north-south spin axis. Compressional waves traversing the inner core along the north-south direction are about 3% faster than those propagating parallel to the equatorial plane. For a summary of the models of inner-core anisotropy parameters, see Song (1997). The strongest evidence for the inner-core anisotropy comes from differential travel times $PKP(BC) - PKP(DF)$ (or simply $BC-DF$) (Creager, 1992; Song and Helmberger, 1993) (an example is given in Fig. 2). Quasi north-south paths show consistent $BC-DF$ travel time residuals, relative to the Preliminary Earth Model (PREM) (Dziewonski and Anderson, 1981), as large as 4 sec at a distance of around 150° (where BC is observable). Because the BC and DF phases have very similar ray paths in the mantle and the outer core, using the differential times greatly reduces the biases from event mislocations and mantle heterogeneity. Although small-scale heterogeneity in the lowermost mantle may still influence the $BC-DF$ times (Breger *et al.*, 1999), the observed large $BC-DF$ anomalies require significant anisotropy in the inner core.

The inner-core anisotropy appears to vary both laterally and with depth. Differential $AB-DF$ times suggest that significant anisotropy appears to extend to the center of the Earth (Vinnik *et al.*, 1994; Su and Dziewonski, 1995; Song, 1996; McSweeney *et al.*, 1997). However, the outermost ~ 150 km of the inner core is nearly isotropic (Shearer, 1994; Song and Helmberger, 1995a,b). There appears to be a sharp transition from the isotropic upper inner core to the anisotropic lower inner core producing a seismic triplication along certain north-south paths (Song and Helmberger, 1998). The inner-core anisotropy appears to vary laterally on a hemispherical scale (Tanaka and Hamaguchi, 1997; Creager, 1999) and on a few hundred kilometers scale (Creager, 1997; Song, 2000a). Vidale and Earle (2000) observed 200 sec of waves scattered from the inner core following the $PKiKP$ arrivals, suggesting strong heterogeneity even on a scale of a few kilometers. If one can assume uniform anisotropy with cylindrical symmetry (despite the strong heterogeneity the inner core seems to exhibit), PKP travel time data seem to favor a tilt of about 10° from the spin axis (Su and Dziewonski, 1995; Song and Richards, 1996; McSweeney *et al.*, 1997), although the resolution of the tilt is poor at present (Souriau *et al.*, 1997).

Mineralogical studies favor ϵ (hexagonal close-packed) over γ (face-centered cubic) iron as the stable phase of iron in the inner core (e.g., Brown and McQueen, 1986; Anderson, 1986; Jephcoat and Olson, 1987; Sayers, 1989; Stixrude and Cohen, 1995). The cause of the inner-core anisotropy is believed to be the preferred orientation of ϵ iron. The

FIGURE 2 A set of short-period (1 sec) *PKP* seismograms from earthquakes in South Sandwich Islands recorded at College, Alaska station over a period of 28 y. Three branches of *PKP* (as labeled) are visible in all the traces: *PKP(DF)* that traverses the inner core, *PKP(BC)* that turns near the base of the outer core, and *PKP(AB)* that turns in the midouter core. The records are plotted with respect to earthquake origin times (from 1967 to 1995) and are aligned with *PKP(BC)*. The *PKP(DF)* and *PKP(AB)* waveforms are windowed out and corrected to a reference distance of 151° and depth of 0 km using the Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson, 1981). The *PKP(DF)* amplitudes are enlarged by 5 times and the *PKP(AB)* arrivals are corrected by $\pi/2$ phase shift. The positive amplitudes of the traces are highlighted for better visual comparisons. The three vertical solid lines mark the predictions of the relative times between the three branches of *PKP* for PREM at the reference distance and depth. The set of seismograms are unusual in the following way. (1) The *PKP(DF)* waves arrive anomalously earlier than the PREM predictions (by about 3 sec), which is believed to be the results of the inner-core anisotropy. (2) It is clear that the *PKP(DF)* waves arrive progressively earlier from the late 1960s to the 1990s (by about 0.3 sec over the 28 y). The time-dependence of the *PKP(DF)* waves from these 38 seismograms was the strongest evidence for the differential rotation of the inner core originally reported by Song and Richards (1996). The dashed line shows the predictions for their best-fitting model of inner core rotation. (3) The *PKP(DF)* amplitudes are anomalous small (about 10 times smaller than the *PKP(BC)* amplitudes) and the *PKP(DF)* waveforms are rather complex, which is observed in many other seismograms along north-south paths (Creager, 1992; Song and Helmberger, 1993). The complexity may be caused by the transitional structure within the inner core (Song and Helmberger, 1998), but no convincing interpretation has been provided.

mechanism, however, for producing such a preferred alignment of iron crystals is uncertain. The proposed models of preferred alignment include two categories: (1) alignment established during the solidification of iron crystals at the surface of the inner core (Karato, 1993; Bergman, 1997); (2) alignment caused by large-scale convective flow in the inner core, under thermal convection (Jeanloz and Wenk, 1988), under differential growth of the inner core (Yoshida *et al.*, 1996), or under Maxwell stress from the magnetic field (Karato, 1999).

6.2 Inner Core Attenuation

The inner core is strongly attenuating: The attenuation is comparable to two other highly attenuating regions of the Earth: the asthenosphere and the shallow crust. The estimated Q_α for the *P* waves in the inner core is around 200–600 from

amplitude ratios between *PKP* branches (Buchbinder, 1971; Sacks, 1972; Doornbos, 1974; Anderson and Hart, 1978; Bolt, 1977; Cormier, 1981; Choy and Cormier, 1983; Bhattacharyya *et al.*, 1993; Niazi and Johnson, 1992; Souriau and Roudil, 1995; Song and Helmberger, 1995a,b; Cormier *et al.*, 1998) and from the underside inner-core reflected waves *PKIIKP* (Masse *et al.*, 1974; Doornbos, 1974; Bolt, 1977).

The estimate of Q_μ from inner core shear modes ranges from 3000 (Buland and Gilbert, 1978; Masters and Gilbert, 1981; Suda and Fukao, 1990) to a much lower value of 110 (Widmer *et al.*, 1991). If the inner core was formed by slow solidification of the outer core as the Earth cooled, one may expect a “mushy zone” of dendrites in the inner core (Fearn *et al.*, 1981; Loper and Fearn, 1983) and Q to increase with depth. The depth dependence of Q in the inner core was inferred (Doornbos, 1974; Choy and Cormier, 1983; Song and

Helmberger, 1995a,b) but remains inconclusive (Cormier, 1981; Niazi and Johnson, 1992; Bhattacharyya *et al.*, 1993).

6.3 Inner Core Shear Waves

Although the solidity of the inner core is well accepted, the direct identification of inner core shear waves, such as *PKJKP* with a shear wave leg *J* in the inner core, remains one of the outstanding problems of seismology. The difficulty of detecting *PKJKP* is caused by the inefficiency of *P*-to-*S* (and *S*-to-*P*) conversion at the inner-core boundary. Detection of *PKJKP* is also hindered by high attenuation at short periods, causing Doornbos (1974) to conclude that the amplitude of *PKJKP* is too small to be observed.

The reported identification by Julian *et al.* (1972) was later thought not to be *PKJKP* because its travel times do not agree with those predicted by normal-mode models. The inner core *S*-wave velocity deduced by Julian *et al.* (1972) is $2.95 \pm 0.1 \text{ km sec}^{-1}$, more than 10% slower than the $3.5\text{--}3.6 \text{ km sec}^{-1}$ reported by Dziewonski and Gilbert (1972) from free oscillations. Recently, Deuss *et al.* (2000) and Okal and Cansi (1998) reported observations of inner core shear waves consistent with an inner core shear velocity of 3.6 km sec^{-1} .

7. Inner Core Rotation

The idea that the solid inner core, at the center of a much larger fluid outer core of low viscosity (Gans, 1972; Poirier, 1988), may rotate differently from the daily rotation of the mantle came from studies of the geodynamo (Gubbins, 1981; Glatzmaier and Roberts, 1995a,b). Electromagnetic torque between the magnetic field generated in the liquid outer core and the conducting inner core is expected to drive the inner core to rotate (Gubbins, 1981; Glatzmaier and Roberts, 1995b, 1996; Aurnou *et al.*, 1996; Kuang and Bloxham, 1997).

Song and Richards (1996) first reported evidence for differential rotation of the inner core from time-dependent *BC-DF* differential times along certain earthquake-station pathways. In particular, they found that the *BC-DF* differential times along the pathway from earthquakes in the South Sandwich Islands (SSI) to the station COL at College, Alaska, have increased systematically over 28 y by about 0.3 sec (Fig. 2). They interpreted the temporal change as evidence for a differential inner-core rotation, which shifts the orientation of the inner core's anisotropy. Assuming a homogeneous inner-core anisotropy model with the anisotropy symmetry (fast) axis tilted from the spin axis (Su and Dziewonski, 1995; Song and Richards, 1996; McSweeney *et al.*, 1997), they estimated the rotation rate to be about 1° y^{-1} .

However, determining the inner-core rotation from the tilt of anisotropy axis may be problematic because the anisotropy

symmetry axis may not be reliably determined (Souriau *et al.*, 1997; Dziewonski and Su, 1998). A much faster rotation rate of 3° y^{-1} was reported by Su *et al.* (1996) from inversions for locations of the anisotropy axis using International Seismological Centre (ISC) arrival times. But a reassessment by Dziewonski and Su (1998) of the temporal variation of the total pattern of the inner core anomalies suggests that the inner-core rotation is not detectable from the ISC data.

Repicking the differential times at COL, Creager (1997) confirmed the time-dependence observed by Song and Richards (1996). He also observed a steep lateral gradient in the anisotropy of the part of the inner core sampled by SSI-Alaska ray paths. He provided an alternative interpretation that the temporal change at COL is caused by a shift of the local velocity gradient from the inner-core rotation and obtained much smaller differential rotation rate of $0.2\text{--}0.3^\circ \text{ y}^{-1}$.

More recent body-wave studies generally support inner-core rotation with a rotation rate of a few tenths of a degree per year. The data at COL were extended to cover a period of 45-years and the time-dependence was found to persist to earlier years (Song, 2000a). In addition, three other stations in Alaska also show systematic increases in differential *BC-DF* times from SSI earthquakes during the past two decades. Surprisingly, the inner-core rotation seems detectable from digital records at the dense Alaska Seismic Network from SSI earthquakes in the 1990s alone (spanning only 8 years). Significant systematic changes in differential *BC-DF* times were also observed from paths from nuclear explosions in Novaya Zemlya in the former Soviet Union to station NVL in Antarctica (Ovchinnikov *et al.*, 1998), and from Alaska earthquakes to the South Pole station (Song and Li, 2000). Weak time-dependence was observed by Li and Richards (1998) in the differential *AB-DF* times from nuclear explosions in Novaya Zemlya recorded at Scott Base, Antarctica. Using a new approach with newly identified inner-core scattered waves, Vidale *et al.* (2000) observed small but coherent shifts in the scattered waves recorded at LASA from two nearby nuclear tests at Novaya Zemlya spanning 3 years. The pattern of the scattered waves suggests a slow inner-core rotation rate of $0.15^\circ \text{ y}^{-1}$.

The claim that the inner core is rotating relative to the mantle faces serious challenges and is under debate. Firstly, some attempts have failed. Souriau (1998a) examined *BC-DF* times from Novaya Zemlya nuclear explosions recorded at DRV, Antarctica over 24 y and did not observe robust temporal change. She concluded that an eastward rotation of 3° y^{-1} (as in Su *et al.*, 1996) is not possible, but a rate of 1° y^{-1} or lower could not be ruled out. Results from normal-mode studies on the inner-core rotation are uncertain. Sharrock and Woodhouse (1998) appear to favor a westward rotation component; but Laske and Masters (1999) found that inner-core rotation is essentially zero (to within 1σ error of $\pm 0.2^\circ \text{ y}^{-1}$) over the last 20 y. Secondly, the detection of the inner-core rotation has been questioned on the grounds of potential biases from event mislocations, mantle heterogeneity, and

heterogeneous event magnitudes (Souriau *et al.*, 1997; Souriau, 1998a,b,c; Poupinet *et al.*, 2000).

In particular, Poupinet *et al.* (2000) used a novel “doublet” technique to examine 12 pairs of *PKP* seismograms from the SSI–COL path. They concluded that the apparent variations with time along the SSI–COL path observed by Song and Richards (1996) are artifacts due to poor earthquake locations. Since the temporal change along the SSI–COL path remains as one of the most convincing observations, the conclusion by Poupinet *et al.* (2000) is very significant in that it questioned directly the existence of a differential inner-core rotation. These criticisms were addressed by Song (2000b, 2001) and Song and Li (2000). Song (2001) suggested that the analyses of Poupinet *et al.* (2000) were flawed; and a re-examination of the SSI–COL path by Song (2000b) using the technique of Poupinet *et al.* (2000) concluded the opposite. Thirdly, theoretical calculations suggest that the inner core may be “locked” to the mantle by gravitational coupling between the mantle and small topography of the inner core induced by mantle heterogeneity (Buffett, 1996) unless the inner core is “soft” so that it continually adjusts its shape as it rotates (Buffett, 1997) or the electromagnetic torque is stronger (Aurnou and Olson, 2000).

With a unique opportunity to observe motions at depth within the core, a detectable inner-core rotation has direct implications for geodynamo studies (e.g., Aurnou *et al.*, 1996; Glatzmaier and Roberts, 1996; Hollerbach, 1998; Sakuraba and Kono, 1999; Aurnou and Olson, 2000).

8. Looking Ahead

From the discovery of the Earth's core less than a 100 years ago to the recent claim of the inner-core rotation, a fascinating journey through the center of the Earth was witnessed in the last century. The breakthroughs made as recently as in the 1990s on many fronts, including core dynamics, high-pressure experiments, and seismology, testify to an equally exciting time ahead. Seismology is likely to continue to play a key role in this journey. We have yet to answer some of the most fundamental questions concerning the core. Is there a low-density stratified layer at the topmost outer core? What is the nature of the low-velocity gradient region at the lowermost outer core? Can seismology resolve the likely small lateral variations in the fluid outer core? Can seismologists directly detect the fluid motions in the core? Can we improve the estimate of the density increase across the ICB? What is the cause of the anisotropy of the inner core? Why are the amplitudes of the inner core arrivals along north–south paths anomalously small and the waveforms complex (Creager 1992; Song and Helmberger, 1993; Fig. 2)? Can we develop high-resolution 3D images of the inner-core anisotropy and heterogeneity? Can we reliably detect inner core shear waves and thus constrain inner core shear wave structure? What is

the nature of the inner core attenuation? Can we confirm the differential inner-core rotation and improve estimates of the rate? Is the inner-core rotation variable on a human timescale? Can we reconcile apparent differences between body-wave studies and normal-mode studies? For example, travel-time data suggest weak anisotropy in the top ~150 km of the inner core whereas strong anisotropy at the top seems to be required to explain the splitting of core-sensitive modes (Durek and Romanowicz, 1999). Would the conclusion of Laske and Masters (1999) change when more high-quality mode data become available in the future? The key to these questions is our ability to isolate influences from mantle and surface structure. So far we have relied on differential travel-time measurements of core phases and/or corrections for mantle structure. With the accumulation of high-quality digital seismic data and the improvement of 3D mantle models, our ability to image the core will undoubtedly improve.

Acknowledgments

Color Plate 1 Map of the global incidence of earthquakes, published in Mallet (1858), from the catalog compiled by himself and his son J.W. Mallet. Based entirely on felt reports, this clearly shows the major non-marine belts of seismic activity; Mallet noted the association of these with large mountain ranges.

Color Plate 2 (a) Zeroth order perturbation contribution in the vertical amplitude, for two singlets of the fundamental spheroidal multiplet ${}_0S_{60}$, computed for the model SAW12D of Li and Romanowicz (1996). The left case corresponds to the singlet with positive deviation of 9.8‰ with respect to the reference frequency, the right case corresponds to the singlet with positive deviation of 3.7‰ with respect to the reference frequency. Note that for the two singlets, the amplitude is localized around a great circle, with $l=60$ oscillations. (b) Higher order perturbations contribution in the vertical amplitude, for the two modes depicted in (a). This amplitude is the result of coupling terms, when coupling along the dispersion branch is taken into account for the 16 closest multiplets. Note that the amplitude variations are large where lateral variations are strong, i.e. in the transition zone between oceanic and continental structure for example. Note also that the amplitude is no longer neither symmetric nor antisymmetric. The contribution of these terms is of same order as the amplitude of the zeroth-order contribution.

Color Plate 3 (a) Snapshots of slip rate at successive instants of time for the spontaneous rupture of an overloaded asperity inside a rectangular fault (solid line). Hotter colors depict larger slip rates. No velocity weakening friction is included. The nondimensional time is listed for each snapshot. The lower right panel shows the slip rate versus time along a line in the in-plane direction intersecting the asperity. The slope of the slanted lines depicts the P - and S -wave velocity. (Reproduced with permission from Madariaga *et al.* 1998, fig. 10, p. 1193.) (b) Same as part (a) but with velocity weakening friction included in the simulation. (Reproduced with permission from Madariaga *et al.*, 1998; fig. 11, p. 1194.) (c) Comparison of snapshots of the dynamic rupture simulation (left) of the 1992 Landers earthquake on the fault plane and the kinematic model (right) recomputed from Wald and Heaton (1994) along a single fault plane. The snapshots depict the horizontal slip rate in 1-second time slices.

Color Plate 4 (a) Snapshots of the shear stress and slip rate fields on a fault containing a very long and narrow asperity (yellow in the stress snapshots). The panels show (from top to bottom) ruptures at sub-critical, slightly super critical and super critical values of the parameter κ . (b) Initial stress field on the Landers fault obtained by trial and error. (c) Slip distribution on the fault for the preferred dynamic model of the Landers 1992 earthquake.

(a)

Global map of the seismic intensity factor

(b)

Global map of largest earthquakes

Color Plate 5 (a) Global map of the seismic intensity factor, I_4 , the average annual number of earthquakes per year during 1964–1995 with magnitudes $m \geq 4$ in each normalized $1^\circ \times 1^\circ$ cell (Kossobokov *et al.*, 2000). (b) The maximum magnitude earthquake that occurred in each normalized $1^\circ \times 1^\circ$ cell during the period 1900–1997. Data for both (a) and (b) are from the NEIC Global Hypocenter Database (GHDB, 1989).

Color Plate 6 Top (Chapter 25, Section 4.3). Images showing the distribution of b values beneath Mt. St. Helens and Mt. Spurr. Each grid element shows the b value for the nearest 100 earthquakes, coloring low b values as blue, normal values as green and yellow, and high values as red. Four samples labeled A–D are plotted to the right of each cross section. These show the actual data used to compute each b value. Note the anomalies (red) at 3–4 km for each volcano and 7–9 km for Mt. St. Helens and 10–13 km for Mt. Spurr. The deeper anomalies are near magma chambers and the shallower ones are at depths of vesiculation of gases. The black line drawing represents a schematic view of the Mt. St. Helens plumbing system (modified from Wiemer and McNutt, 1997). **Bottom** (Chapter 25, Section 5.3). (a) An example seismogram of a small eruption (whoosh) at Arenal volcano, followed by rhythmic degassing (chugs), followed by harmonic tremor. The eruption ejected ash to 500 m above the crater and the chugs were audible at 2.8 km for 25 sec. (b) Seismogram and spectrogram from April 1994 showing three small eruptions. The blue colors show low signal levels, the yellow intermediate, and the red strongest. The spectra are dominated by narrow peaks spaced regularly in frequency, each of which changes frequency systematically with time. Spectrogram vertical scale is 0 to 8 Hz, and horizontal scale is 3600 sec (1 h) (modified from Benoit and McNutt, 1997).

Color Plate 7 Map view of synthetic *P*-wave checkerboard model (a,c) and the synthetic reconstruction (b,d) at selected depths. East-west cross-section of a synthetic *P*-wave checkerboard model (e) and the synthetic reconstruction (f). The location of the cross-section is shown in (b). To aid in the comparison of the “true” and reconstructed velocity models, cells that are not sampled in calculating the synthetic arrival-times and in the synthetic reconstruction are blanked out (white). Earthquakes that are located within the layer are plotted (open circles). Earthquakes that lie within ± 2 km of the cross-section are plotted (filled circles). See the text for a description on the generation of the checkerboard velocity model and calculation of the synthetic arrival-times.

Color Plate 8 Map view of the P -wave velocities at selected depths between 1 to 15 km. The seismic stations used to monitor seismicity and major faults, fissures, vents and calderas are shown for reference. Cells not sampled by any ray are not plotted.

Color Plate 9 **Top** (Chapter 27, Section 3.1). Crustal structure models across the western Nankai trough axis together with micro-seismicity determined by land network (see Fig. 1B) (from Kodaira *et al.*, 2000a,b). Also, estimated rupture portion along plate boundary of the 1946 Nankaido Earthquake (M_W 8.2) is shown. Anomalous structure beneath Tosa-bae (top panel) is interpreted to be due to seamount subduction. Bottom panel (about 50 km westward) has no such feature. **Bottom** (Chapter 27, Section 3.2). Across-arc crustal model of northern Izu–Ogasawara arc (from Suyehiro *et al.*, 1996). Combined OBS and MCS investigations revealed the 2D image of the Pacific plate subduction and oceanic island arc crust. Copyright American Association for the Advancement of Science.

Color Plate 10A (a) Fault plane solutions in eastern Turkey, NW Iran and the Caucasus. Red focal spheres are those constrained by body-wave modeling, black ones are Harvard CMT solutions for additional earthquakes with $M_w \geq 5.3$ and with more than 70% double-couple component (see Appendix), and gray spheres are other earthquakes whose mechanisms are based on long-period first-motion polarities. Important patterns here include: (1) low angle thrusting on both sides of the Greater Caucasus (GC) and in the SW corner of the Caspian Sea; (2) NW–SE right-lateral strike-slip faulting in a belt from the northern Zagros mountains (Z), through the regions between Lakes Urmieh (LU) and Van (LV) to join with the North Anatolian Fault (NAF). The East Anatolian Fault is marked EAF. (b) Earthquake slip vectors taken from the mechanisms in (a), with the same colour code for red and black arrows and with white arrows representing the slip vectors from the first-motion (gray) solutions. Some slip vectors have been omitted, where the choice of nodal plane is uncertain. Examples of the separation of strike-slip and convergent components of motion (‘partitioning’) occur on different scales. At the largest scale, the overall oblique convergence between Arabia and Eurasia (large white arrows) is separated into strike-slip in the south and shortening in the eastern Great Caucasus, with approximately orthogonal slip vectors. At smaller scales, nearly perpendicular slip vectors on adjacent strike-slip and thrust earthquakes are seen in the Alborz (A) and near the Main Recent Fault (MRF) in the NW Zagros. (c) Velocities of various points relative to Eurasia, determined by GPS (from McClusky *et al.*, 2000).

Color Plate 10B (a) Fault plane solutions in central Greece and the western Aegean. Red focal spheres are those constrained by body-wave modeling. Black focal spheres are Harvard CMT solutions for additional earthquakes with $M_w = 5.3$ and with more than 70% double-couple component (see Appendix). Plio-Quaternary and active faults trends are marked, with those thought to be currently active shown in thicker lines. HT is the Hellenic Trench. Bathymetric contours are shown at 500, 1000, 2000 and 3000 m. Note how the NE-SW right-lateral strike-slip faults in the northern Aegean change abruptly to E-W normal faults in central Greece. (b) Slip vectors for earthquakes shown in (a), with red arrows from body-wave solutions and black ones from CMT solutions. Note the abrupt change in slip vector direction where the strike-slip faulting changes to normal faulting in central Greece. (c) Velocities relative to Eurasia, determined by GPS. Black arrows are from Clarke *et al.* (1998), red arrows are from McClusky *et al.* (2000). Note that the change in slip vector direction in central Greece is not seen in the velocity azimuths.

Color Plate 11 **Top** (Chapter 34, Section 3): Directions of maximum horizontal stress from the World Stress Map database superimposed on global topography and bathymetry. Only A and B quality data are shown. Data points characteristic of normal faulting are shown in red, strike-slip areas are shown in green, reverse faulting areas are shown in blue and unknown stress indicators are shown in black. **Bottom** (Chapter 34, Section 4): Generalized world stress map based on the data in Color Plate 12 and similar to that of Zoback (1992). Inward pointed arrows indicate high compression as in reverse faulting regions. Paired inward and outward arrows indicate strike-slip faulting. Outward directed red arrows indicate areas of extension. Note that the plates are generally in compression and that areas of extension are limited to thermally uplifted areas.

Color Plate 12 (Chapter 34, Section 4). Directions of maximum horizontal stress from the World Stress Map database. Colors are the same as in Color Plate 11 (top). Only A and B quality data are shown.

Color Plate 13 Apparent stress versus seismic moment (M_0). Data sources: KTB borehole events, Zoback and Hartjes (1997); South African mine tremors, McGarr, 1999; Cajon Pass, Abercrombie (1995); Southern California, Kanamori *et al.* (1993). Modified from McGarr (1999).

Color Plate 14 Coseismic deformation field for the Landers earthquake measured by INSAR. (a) Observed “wrapped” interferogram, shown as 28-mm fringes. (b) Observed “unwrapped” interferogram in mm (Trouvé, 1996; Trouvé *et al.*, 1998). (c) Residual (observed minus calculated) wrapped interferogram, shown as 28-mm fringes. (d) Residual unwrapped interferogram in mm. The interferogram is calculated from ERS-1 SAR images taken before (April 24, 1992) and after (June 18, 1993) the earthquake (Massonnet *et al.*, 1994). Each fringe in parts a and c denotes 28 mm of change in range. Here, the altitude of ambiguity h_a exceeds 1500 m.

Centennial Earthquake Catalog (1900–1999)

Color Plate 15 Global earthquake locations from 1900 to 1999 taken from the centennial catalog. Bathymetry/topography are from the database of Smith and Sandwell (1997). Earthquakes relocated in this study are shown by filled circles and unrelocated earthquakes by filled hexagons. Symbol fill is color-coded according to focal depth h : red = shallow events ($h < 70$ km); yellow = intermediate ($70 \leq h < 350$ km); and blue = deep ($h \geq 350$ km). A thick symbol outline is used for events with magnitudes greater or equal than 8.0.

Color Plate 16 Earthquake locations from 1900 to 1999 for the Arctic region, taken from the centennial catalog. Bathymetry/topography are from the database of Jakobsson *et al.* (2000). Same symbols as in Color Plate 15.

Color Plate 17 Locations of deadly earthquakes of the world: 1500–2000. Population density data was from the US Oak Ridge National Laboratory, 1999.

Color Plate 18 A method to assess parameters (Gasperini *et al.*, 1998).

Color Plate 19 Approximate RF VIII or equivalent isoseismal areas of some major historical earthquakes of India. Generalized tectonic features are adapted from Gansser (1964, 1983). (On account of the large scale of the map, the isoseismal areas are only approximate. For exact details, the reader must refer the figures prepared for the individual earthquakes.)

Color Plate 20 The global shear velocity tomography model SB4118, obtained using a large data set of body wave differential times, surface wave dispersion measurements, and free oscillation splitting functions. (Adapted from G. Masters *et al.*, 1999.)

Color Plate 21 (a) Best focused crosswell survey geometry found. Figure key similar to Figure 4 of Chapter 52, but here shading also illustrates the resolution of each model cell (best resolution in darker shades). In this example only six sources (boxes with stars) and receivers (empty boxes) were used. Crosses show model cells on which the survey was focused. (b) The relative shear velocity perturbation under North America in three layers at depths between 25 and 300 km as determined by Alsina *et al.* (1996). (c) 40 s period fundamental mode Rayleigh phase velocity map from Curtis *et al.* (1998). Inset: slice of the *P*-velocity anomaly through the model of Bijwaard and Spakman (2000) at 53 km depth. Major tectonic boundaries shown in yellow, c – Caucasus, p – Pamir, k – Karakoram, ts – Tien Shan, him – Himalayan arc.

Color Plate 22 Isotropic components of an isotropic (top) and a transversely anisotropic (bottom) tomographic cross-well inversion. Wells are approximately vertical at 0 and 100 m. Left and right hand sides show slowness logs from left-hand well (structures are roughly flat-lying). Colour coding represents slowness (blue ≈ 0.2 ms/m, red ≈ 0.34 ms/m).
